Connective tissue diseases in children

■ LUCY R. WEDDERBURN ■ CLARISSA A. PILKINGTON ■ MICHAEL W. BERESFORD

- Connective tissue diseases of children differ from their adult counterparts in important characteristics, including presentation, course, subtypes, responses to therapy, and morbidities.
- Juvenile-onset systemic lupus erythematosus is a severe, relapsing, chronic multisystem disease, characterized by widespread inflammation and damage to any organ. There is a marked difference in the pattern of organ involvement compared with adult-onset disease, with more severe disease in childhood.
- Juvenile dermatomyositis is a complex multifactorial disease whose management requires participation of a wide range of specialists over many years; better recognition to aid rapid diagnosis and international collaborative efforts will ultimately lead to more individualized treatment choices and improved outcomes.
- Localized linear scleroderma is the most common form of childhood scleroderma and can show good response to corticosteroid and immunosuppressant therapy.
- Management of these disorders has been hampered by severe lack of an evidence base; significant progress is now being made in determining the specific characteristics of these pediatric diseases, including describing etiopathogenesis, developing disease activity measures and outcome scores, and establishing the best treatment modalities.
- Caring for children and young people with these complex diseases requires an age-appropriate and multidisciplinary approach to encompass developmental, growth, and family needs of the patient.

INTRODUCTION

Connective tissue diseases of children include a wide range of multisystem disorders, most of which may present with multiple and varying symptoms. The pediatric connective tissue diseases include juvenile dermatomyositis, juvenile systemic lupus erythematosus, childhood scleroderma, and a range of overlap disorders and less clearly differentiated conditions. Although these diseases have parallel conditions in adults (e.g., systemic lupus erythematosus and dermatomyositis), they also differ from their adult counterparts in presentation, course, subtypes, responses to therapy, and morbidities. The treatment of children and young people with complex disease requires an age-appropriate and multidisciplinary approach to encompass developmental, growth, and family needs of the patient. Chronic disease in young people affects the child's whole physical and emotional development; thus time devoted to discussing all aspects with children, young people, and their families is essential. In addition, it is increasingly recognized that pediatric connective tissue disorders may be active well into adult years or may produce lifelong sequelae, such as increased risk of cardiovascular disease.

This chapter focuses on childhood lupus, dermatomyositis, and scleroderma. As well as these delineated conditions, children with connective tissue diseases frequently have features of more than one connective tissue disorder, so that their disease is said to "overlap." An example is a child with juvenile dermatomyositis with features of scleroderma, such as Raynaud phenomenon. Additionally, it is well recognized that these conditions may evolve, with new features appearing over time that may be more typical of a different disease. For example, children with arthritis may develop lupus-like features. Such overlap between connective tissue disorders means that children need to be carefully assessed and reexamined on a regular basis.

JUVENILE-ONSET SYSTEMIC LUPUS ERYTHEMATOSUS

Juvenile-onset systemic lupus erythematosus (JSLE) is a severe, relapsing, chronic multisystem disease, characterized by widespread inflammation and damage to any organ. It is lifelong and potentially life threatening, and at present there is no cure.

Epidemiology

Robust epidemiologic data in childhood are lacking. Overall, 15% to 20% of patients with lupus develop the disease in childhood, but its true annual incidence is unknown. Prevalence rates vary widely between 4 and 250 per 100,000, with greater prevalence in Afro-Caribbean, Asian, Latino, and Native American children. The female-to-male ratio (approximately 5:1) is lower in the pediatric population than in adult-onset disease, especially in prepubertal children. Male gender, early onset of disease, and nonwhite ethnicity are all associated with worse outcome.

Etiopathogenesis

JSLE is the archetypal pediatric systemic autoimmune disease. Its cause remains unknown. Hormonal and environmental factors act on genetically prone individuals over time, which results in the development of autoimmunity and disease progression.¹ Hormonal influences are less likely to play a significant role in children who develop lupus before puberty. JSLE is more common in children with genetic defects of the immune system, including complement deficiencies and selective immunoglobulin A deficiency. Rare genetic disorders associated with pediatric lupuslike syndromes offer important insight into immune dysregulation resulting in lupus development.

Few studies have investigated the specific immunopathologic characteristics of JSLE; increased apoptosis and defective clearance of apoptotic material probably contribute to the pathogenesis. Neutrophil apoptosis is significantly increased and dysregulated in JSLE patients compared with control subjects.² Increased Toll-like receptor expression triggered by auto-antigen binding induces an interferon- α response.³ JSLE patients demonstrate a strong type I interferon signature.⁴

Clinical presentation

Lupus is a complex illness at any age. Diagnosis can be particularly challenging during childhood and adolescence. Extremely variable in its clinical manifestations, it ranges from a relatively mild to a severe life-threatening illness.⁵ Its nonspecific features, including fever, fatigue, weight loss, mouth ulcers, arthralgia, and headaches, often occur in children for other reasons. Revisions to the American College of Rheumatology (ACR) classification criteria for lupus⁶ need to be formally assessed in the pediatric age group. Failure to meet ACR criteria at time of presentation does not exclude lupus; individuals with two or three features may develop others later. A marked difference is noted in the pattern of organ involvement and severity in JSLE compared with adult-onset disease (Table 105.1).^{7,8} The butterfly rash may be subtle or absent in children (Fig. 105.1), but many exhibit marked photosensitivity. Cardiopulmonary manifestations in JSLE are increasingly recognized. Significantly more major organ disease occurs in childhood, especially at diagnosis, including hematologic, renal, and neurologic involvement.⁸ Hematologic involvement is frequent. Neuropsychiatric manifestations are common and need careful evaluation. They cause significant long-term morbidity, manifesting as headaches, mood disturbance, confusion, seizure activity, psychosis, and aseptic meningitis. Renal involvement

TABLE 105.1

Difference in pattern of presentation, disease severity, and damage between childhood- and adult-onset systemic lupus erythematosus

	Childhood onset (n = 67)	Adult onset (n = 131)	P value
Duration of follow-up (in years, mean ± SD)	3.2 ± 2.0	3.5 ± 2.6	
Patients with any renal involvement	52 (78%)	68 (52%)	.0005
Oral prednisolone	65 (97%)	92 (70%)	<.0001
Pulse methylprednisolone	20 (30%)	15 (11%)	.001
Immunosuppressive medications	44 (66%)	48 (37%)	.0001
SLEDAI score at diagnosis (mean ± SD)	16.8 ± 10.1	9.3 ± 7.6	<.0001
Adjusted mean SLEDAI score (mean ± SD)	5.70 ± 2.68	4.59 ± 3.05	.012
Adjusted mean renal SLEDAI score (mean ± SD)	2.37 ± 2.38	0.82 ± 1.59	<.0001
Mean SDI score at end of follow-up (mean ± SD)	1.70 ± 2.67	0.76 ± 1.16	.008

SD, standard deviation; SDI, Systemic Lupus International Collaborating Clinics/American College of Rheumatology Damage Index; SLEDAI, Systemic Lupus Erythematosus Disease Activity Index. Adapted from Brunner HJ, Gladman DD, Ibanez D, et al. Difference in disease features between childhood-onset and adult-onset systemic lupus erythematosus. *Arthritis Rheum* 2008;58:556-62.

Fig. 105.1 Cutaneous manifestations of juvenile-onset systemic lupus erythematosus. (a) Severe confluent, photosensitive, erythematous malar or “butterfly” rash in a 7-year-old boy with grade IV lupus nephritis and C1q deficiency. (b) Symmetrically distributed, maculopapular, erythematous to violaceous, pruritic rash in the same child, also on the trunk, with accentuation in ultraviolet light—exposed areas and typical sparing of the knuckles. (c) Widespread symmetric facial erythema, edema, and malar rash with typical nasolabial sparing in a teenage girl with severe cutaneous, pulmonary, and hematologic involvement. (d) A wide range of other skin manifestations may be noted, including nail-fold capillary changes, vasculitis, and chilblainlike lesions, nodules, and erythematous plaques.

occurs very frequently in JSLE.⁹ Children with lupus are at particular risk of infection, which is associated with a worse prognosis, from the disease process itself and use of immunosuppressants. Pneumococcal sepsis is a particular risk, and vaccination is recommended.

Assessment of disease severity and monitoring of outcome

Optimizing disease control depends on assessing disease activity, but the complexity and variability of pediatric lupus make this difficult.⁵ Numerous composite scores have been developed for adult SLE to standardize assessment of disease activity, and many are being used in JSLE. The Systemic Lupus Erythematosus Disease Activity Index, Systemic Lupus Activity Measure, and British Isles Lupus Assessment Group score are all highly sensitive to clinical change in children. A disease activity score is a component of the validated Pediatric Rheumatology International Trials Organization pediatric lupus disease activity core set and is included in a proposed definition of response to therapy.¹⁰ Preliminary criteria have been developed for global disease flare in JSLE.¹¹

It is important to assess patients carefully for complications associated with JSLE and adverse effects arising from their therapy. Building on the adult-based Systemic Lupus International Collaborating Clinics/American College of Rheumatology Damage Index (SDI), a preliminary core set of JSLE measures of damage highlights important differences in pediatrics.¹⁰

SDI modifications for JSLE include growth and development assessments, and need prospective validation.¹² These modifications, and the potential for repair in children, challenge the concept of permanency of damage in JSLE. Adding pediatric-specific domains and revising existing SDI domains to reflect the specific characteristics of JSLE will promote accurate follow-up of patients through to adulthood. Careful clinical assessment, knowledge of normal variation with age, and ability to communicate well with young patients is vital.

Management

The challenges of pediatric practice are especially important in treating lupus patients. The holistic approach to managing JSLE patients increasingly recognizes the specific obligations to provide an expert, multidisciplinary team of specialized health care workers looking after young people and their families. Close collaboration with other specialists is important. The key goals of managing patients with JSLE are to control or abolish inflammatory disease activity, to maintain function and quality of life as they grow and develop, to minimize risk of permanent organ damage (resulting from the disease, its treatment, or complications), to minimize other treatment-related adverse events, and to prevent premature death.

A major difference from adult practice in managing patients with JSLE is lack of a robust evidence base with no controlled clinical trials of any drugs commonly used. Intensive drug regimens are frequently instigated

based on adult data, clinician's experience, retrospective case series, and best-practice guidelines. Adverse effects of these drugs, together with the disease, contribute to associated morbidity, including organ dysfunction, premature ovarian failure and infertility, malignancy, osteoporosis, accelerated cardiovascular disease, and severe and/or recurrent infections. Poor adherence to the treatment regimen is often a major problem. Drug formulation and dosing schedule are also crucial to consider. Less toxic regimens of new drugs and/or combinations of existing drugs that allow reduced dosage are needed. Despite the lack of clinical trials, hydroxychloroquine is widely used in JSLE in view of beneficial outcomes shown in adult studies.¹³ Of particular relevance to long-term care of JSLE patients, hydroxychloroquine has been demonstrated to reduce flare rate and damage accrual; to prevent or alleviate cutaneous and articular manifestations; to have steroid-sparing, cholesterol-lowering, and antiatherogenic effects; and to maintain lupus nephritis remission.

Glucocorticoids remain the mainstay of initial JSLE treatment when there is significant organ involvement. The safest dose, route, frequency, and weaning regimen of steroids remain unknown in JSLE.¹³ However, pulse methylprednisolone (30 mg/kg/day up to a maximum of 1 g for 3 days), repeated after a week and then weekly for up to 6 weeks is a standard induction regimen widely used, along with a weaning dose of oral prednisolone, starting at between 1 and 2 mg/kg/day. In moderate to severe disease, immunosuppressive agents are needed. Methotrexate is steroid sparing and improves mucocutaneous and articular disease in adults; its effect in JSLE is mixed. Azathioprine is widely used in JSLE as a corticosteroid-sparing agent; in cutaneous, hematologic, or renal disease; or after standard cyclophosphamide therapy in lupus nephritis.

The gold standard until recently for treating major organ involvement has been monthly intravenous pulse cyclophosphamide for 6 months, followed by quarterly infusions for up to 2 years.¹³ Small, nonrandomized studies have demonstrated improved renal parameters in lupus nephritis treated with cyclophosphamide.¹⁴ Although cyclophosphamide is better tolerated in younger people, nausea, hair thinning, and infection can be troublesome. Premature gonadal failure is a serious potential complication, although risks are lower among younger women and prepubertal girls with current treatment regimens. Fertility issues are more significant for adolescent males, in whom there is some evidence of reduced fertility even without cyclophosphamide. Risks and benefits, and potential sperm banking before treatment of older teenagers, needs careful discussion.

Mycophenolate mofetil is a widely used alternative for moderate to severe renal and nonrenal disease. It is generally well tolerated with a better safety profile and shows beneficial effects especially in renal disease. To date, experience with mycophenolate mofetil in JSLE is limited, although it offers a significant therapeutic opportunity by being corticosteroid sparing, improving renal function, and reducing disease activity.¹⁵ Recently developed consensus treatment plans for lupus nephritis aim to improve outcome and support conduct of comparative effectiveness studies aimed at optimizing therapeutic strategies.¹⁶

Biologic therapies offer great therapeutic potential in JSLE, although randomized controlled trials of their safety and efficacy are warranted. A number of these are now under way, including a phase 2 trial of belimumab, a human monoclonal anti-BLyS antibody (<http://clinicaltrials.gov/ct2/show/NCT01649765>). Rituximab, a chimeric mouse-human monoclonal antibody resulting in B-cell depletion, has been used in a number of open-label studies for treatment of JSLE¹⁷; results indicate that it can be effective in combination with standard immunosuppressive agents, although safety issues and reemergence of underlying disease may occur.

Clinical severity and outcome

Comparisons with SLE in adult cohorts demonstrate that JSLE is more severe, with greater disease activity, higher cumulative SDI scores, and greater renal damage accrual.^{7,8} Greater use of corticosteroids and immunosuppressant drugs in JSLE and their associated adverse effects emphasize the importance of developing more effective treatments for JSLE. Ten-year survival, which has markedly improved over recent decades, is now approaching 90%. Despite this, mortality in JSLE is higher than in adult SLE, and JSLE remains a devastating disease.

Neonatal lupus syndrome

Neonatal lupus syndrome is caused by transplacental passage of maternal autoantibodies to SSA/Ro and SSB/La to the fetus.¹⁸ Regular fetal monitoring from 16 weeks' gestation is mandatory in all affected mothers to detect evidence of cardiac conduction defects, and careful postnatal monitoring is essential. Skin, hepatic, and hematologic manifestations are self-limiting and

resolve. Cardiac disease can be fatal. Heart block is typically permanent, often requiring cardiac pacing. Affected infants are at an increased risk of subsequent autoimmune disease.

THE PEDIATRIC INFLAMMATORY MYOPATHIES: JUVENILE DERMATOMYOSITIS

Juvenile dermatomyositis (JDM) is the most common of the pediatric idiopathic inflammatory myopathies; it typically presents with proximal muscle weakness and rash but frequently affects other organs. Because JDM is a complex multisystem disease, management requires a multidisciplinary team of experts and is aimed at early recognition and aggressive treatment to prevent complications. Proximal weakness in a child needs to be distinguished from an acute infectious process, a neuromuscular disease such as a dystrophy, or myositis that is part of another connective tissue disorder. Other idiopathic inflammatory myopathies, including juvenile polymyositis, in which there is no rash, inclusion body myositis, and eosinophilic myositis, are rare in children.

Epidemiology

The annual incidence of JDM is 2 to 3.5 per million per year with some differences between ethnic groups.^{19,20} Mean age at onset is around 7 years of age,²¹ although JDM may begin at a very young age. JDM is more common in girls (approximate female-to-male ratio of 2.3:1), but there is a lower ratio in children with disease onset at younger than 5 years.^{20,22}

Etiopathogenesis

The pathogenesis of JDM is unknown. A working hypothesis is that environmental triggers affect the immune system of genetically susceptible individuals, leading to damage of capillaries and small vessels of skin, muscle, and other organs.²³ Typical pathologic features in affected muscle are endothelial and small-vessel abnormalities, including capillary dropout, inflammatory changes, muscle fiber major histocompatibility complex (MHC) class I protein overexpression, muscle fiber regeneration or necrosis, and fiber atrophy (Fig. 105.2). An international consensus group has proposed a system to score severity of JDM in biopsy specimens in four domains: vascular/endothelial changes; inflammatory signs; muscle fiber abnormalities, including MHC class I overexpression; and connective tissue changes.²⁴

Like other idiopathic inflammatory myopathies, JDM is a complex disease with polygenic effects, and so large cohorts are required for genetic study; this has been facilitated by large collaborative cohort studies in recent years.^{25,26} The genetic region with the strongest associations for JDM is the human leukocyte antigen (HLA) region: thus HLA-B*08, DRB1*0301, and DQA1*0501 (the extended ancestral haplotype) confer risk of adult and pediatric myositis, and HLA-DPB1*0101 confers independent risk of myositis in particular serologic subgroups. Several HLA alleles, including DQA1*0201, DQA1*0101, and DQA1*0102, are protective in JDM.²⁷ Other loci that may confer risk include the cytokine genes for tumor necrosis factor- α (TNF- α), interleukin-1 α , and interleukin-1 β . Evidence suggests that genes that confer risk for many autoimmune conditions, such as *PTPN22*, are also associated with JDM.²⁸ A recent genomewide association study of both adult and childhood dermatomyositis confirms that many genes known to confer risk of other autoimmune diseases such as diabetes are also associated with myositis.

Autoantibodies are common in JDM; up to 70% of cases are antinuclear antibody positive. The autoantibody profile of both myositis-specific and myositis-associated antibodies in adult and childhood idiopathic inflammatory myopathies is tightly linked with HLA haplotypes and specific autoantibodies associate with particular clinical phenotypes.²⁹ Thus antisynthetase antibodies associate with joint involvement; anti-PM-Scl, with scleroderma-like features; anti-Jo-1, with lung disease; and anti-Mi-2, with classic rashes and milder disease. Recently identified autoantibodies in JDM include anti-p155/140 antibody, present in 23% to 29% of cases and associated with more severe skin involvement and lipodystrophy, which in adults is associated with risk of cancer. Another recently discovered antibody, anti-p140, confers risk of calcinosis in JDM.²⁹ It is not clear whether these antibodies are themselves pathogenic, although immunoglobulin G and complement deposition on small vessels has long been recognized in JDM. However, even in the absence of a direct pathologic role, autoantibodies may provide valuable diagnostic and prognostic tools in the future.

Although triggers of JDM remain unknown, several studies have suggested that infections are common before onset. Evidence from gene expression profiling in muscle tissue suggests a strong type I interferon signature

Fig. 105.2 Histologic features seen on muscle biopsy tissue from patients with juvenile dermatomyositis. (a) Variation in fiber size, fiber necrosis, perifascicular atrophy, inflammatory infiltrate (arrow), and increased numbers of internal myonuclei. (b) A necrotic fiber (single arrow) and a fiber with features of regeneration (double arrows) in a high-power photomicrograph. (c) Expression of neonatal myosin, predominantly in a perifascicular pattern. (d) Increased sarcolemmal expression of major histocompatibility class I protein on muscle fibers. (e) Infiltrating T lymphocytes (CD3+) in a perivascular pattern. (f) Infiltrating myeloid cells (CD68+), both perivascular and diffusely infiltrating. (g) Capillary density depletion, as indicated by CD31-stained capillary endothelium. (h) Increased endomysial and perimysial connective tissue deposition. (a and b, hematoxylin-eosin; c to g, immunohistochemical staining for markers as shown; h, Gomori trichrome stain.)

that would support a viral trigger.³⁰ Interferons, likely produced within the muscle by infiltrating dendritic cells,³¹ are powerful mediators of MHC protein upregulation, a characteristic feature of JDM muscle.³² MHC protein overload may contribute to endoplasmic reticulum stress, which is highly damaging to muscle tissue.

Clinical presentation and features

Classic cases of JDM present as proximal muscle weakness and rash, most typically a rash over the knuckles (Gottron papules) and/or a heliotrope rash around the eyes (Fig. 105.3). Onset may be rapid, or slow and insidious, the latter making diagnosis difficult. JDM may present with less typical rashes on the face, extensor surfaces, or axillae. Early ulceration and calcinosis are poor prognostic signs.³³ Nail-fold capillary changes and periungual erythema are common and suggest ongoing active disease. Nail-fold capillaroscopy is a sensitive, easy-to-use bedside investigation that may show typical dilated capillary loops and capillary dropout (see Fig. 105.3).

Diagnostic criteria for JDM, still those of Bohan and Peter,³⁴ require rash with symmetric proximal muscle weakness, raised serum muscle enzyme levels, and abnormal findings on muscle biopsy and electromyography. However, because magnetic resonance imaging (MRI) is increasingly the investigation of choice and electromyography is now rarely performed in children, these criteria are no longer representative of current practice. International efforts to generate more appropriate modern criteria are under

way. A protean range of other clinical features may occur in JDM at presentation or during disease. These include arthritis (approximately 60% of cases), Raynaud phenomenon (which in affected children shows overlap with scleroderma), dysphagia, dysphonia, fevers, mood changes, irritability, anorexia, and abdominal symptoms (Table 105.2).

Assessment and monitoring

History taking, examination, investigation, and ongoing assessment of children with JDM are ideally performed in specialist centers. Muscle strength should be assessed using a validated method such as the Childhood Myositis Assessment Scale (CMAS) or manual muscle testing of a standardized set of muscles (MMT8). Skin involvement should be carefully sought and documented—not only the typical rash but also edema, ulceration, nail changes, and calcinosis. Several tools for skin assessment in JDM have been proposed, including the Cutaneous Assessment Tool (CAT)³⁵ and the skin domains of the Disease Activity Score (DAS).³⁶ Work by the Pediatric Rheumatology International Trials Organization and the International Myositis Assessment and Clinical Studies Group led to proposed core sets of measures of disease activity and damage in JDM^{10,37} that are being validated³⁸; both include parent/patient assessment, physician's overall assessment, muscle strength measurement, functional assessment, and assessment of extramuscular disease.²⁷ Recently criteria for remission have been proposed.³⁹ At presentation, laboratory measurement of blood cell count,

Fig. 105.3 Skin and nail involvement in juvenile dermatomyositis (JDM). (a) Classic Gottron papules over metacarpophalangeal and distal and proximal interphalangeal joints. (b) Periungual erythema and nail-fold capillary loops. (c) Scaly erythematous rash over knees that may be mistaken for other conditions, such as psoriasis. (d) Facial rash in a periocular and nasal distribution, including across the bridge of the nose in a child requiring nasogastric feeding due to dysphagia and risk of aspiration. (e) Close-up of facial rash in same child as in (d). (f) Scarring lesions in a child with JDM with ulcerative skin disease.

erythrocyte sedimentation rate, levels of serum muscle enzymes (creatinine kinase, alanine transaminase, and aldolase if available), autoantibodies, immunoglobulins, and renal and hepatic function should be performed; the latter are also important for drug monitoring. Assessment of autoantibodies may help to delineate overlap disease, such as JDM-scleroderma or JSLE. In the future, autoantibodies may prove useful as prognostic biomarkers in JDM. The use of markers of endothelial activation to measure JDM disease activity is a novel area to date.²⁷ Muscle biopsy can provide useful diagnostic information and helps exclude differential diagnoses such as the dystrophies but is not used in all centers. Quantitative MRI findings can correlate with clinical disease activity,⁴⁰ but protocols are not yet standardized. Specific investigation of complications, such as videofluoroscopy in cases of suspected pharyngeal involvement or high-resolution computed tomography with respiratory involvement, should be considered. Regular monitoring of disease activity over time by measurement of muscle strength, examination of skin and nail folds, and quantification of functional status is vital. Serial MRI assessments may prove sensitive to detect flare of disease, whereas determination of serum enzyme levels is less useful once treatment has been initiated.

Management and outcome

The management of JDM is hampered by a scant evidence base; there are no published randomized controlled trials in JDM, although some are under way. Data from a randomized trial to study the addition of methotrexate or cyclosporine to prednisolone compared with prednisolone alone, given at diagnosis, are currently being analyzed (www.printo.it). The mainstay of treatment remains corticosteroids, usually combined with a disease-modifying antirheumatic drug (DMARD), most commonly methotrexate at a dose of 15 mg/m² per week, preferably given subcutaneously. Because evidence suggests that gastrointestinal involvement leading to poor oral absorption is common, corticosteroids are ideally initially given

intravenously. Pulse methylprednisolone (30 mg/kg/day up to a maximum of 1 g, for 3 days, repeated after a week) is given along with weaning doses of oral prednisolone, starting at 1 to 2 mg/kg/day. Evidence suggests that early use of methotrexate with corticosteroid reduces overall corticosteroid dose and long-term adverse effects such as osteoporosis and growth retardation, while providing disease control as good as that with a corticosteroid alone.⁴¹ Other DMARDs used in some centers include azathioprine (3 to 5 mg/kg/day); hydroxychloroquine (3 to 6 mg/kg/day), especially for rash; cyclosporine (total of 4 to 10 mg/kg/day in two divided doses, with the goal of a trough level of 75 to 100 ng/mL), and mycophenolate mofetil (starting at 150 mg/m² bid, and gradually increasing to a maximum oral dose of 600 mg/m² bid).⁴² Intravenous immune globulin has been shown to provide clinical benefit in a controlled trial in adults and in a number of series in JDM. Recently consensus-based protocols for treatment of JDM have been developed⁴³; with standardized treatment and data collection, it may be possible to assess such treatment protocols outside of conventional randomized controlled trials.

As well as medication, intensive physiotherapy assists in maintaining and restoring muscle strength, and there is evidence that this is safe in JDM.⁴⁴ Use of photoprotection for skin must be emphasized. Other interventions, such as nasogastric tube feeding in cases of dysphagia, speech and language therapy in cases of dysphonia, and specialist skin care, may be needed.

For severe or refractory cases various therapeutic options exist, with the choice being led largely by local experience. Cyclophosphamide, given intravenously monthly at 0.5 to 1 g/m², was shown to be beneficial in a series of refractory cases of JDM with severe features, including severe weakness, dysphagia, skin or gastrointestinal ulcerations, or central nervous system disease.⁴⁵ More recently, severe cases have been treated with biologic agents, including TNF blockers (etanercept and infliximab) and the B-cell-depleting monoclonal antibody rituximab.⁴⁶ The first international randomized controlled trial of rituximab in myositis included adults and children but failed to reach its primary endpoint; however, the data

TABLE 105.2
Clinical features of juvenile dermatomyositis

Feature	Approximate frequency (%)
Musculoskeletal	
Weakness	85-100
Myalgia	62-73
Arthritis/arthralgia	6-66
Raynaud phenomenon	14-25
Mucocutaneous	
Gotttron papules	57-100
Heliotope rash	66-99
Malar or facial rash	42-73
Other rash	
Skin ulceration	23
Calcinosis	6-30
Nail-fold changes	50-91
Mouth ulcers	25-35
Lipoatrophy	10-21
Edema	11-36
"V" sign	2
Gastrointestinal	
Dysphagia	18-44
Dysphonia	17-43
Abdominal pain/discomfort	21-37
Respiratory	
Dyspnea	18-47
Constitutional	
Fevers	16-65
Mood change, irritability	11-45
Fatigue, lethargy	10-85

Figures with wide ranges reflect values from various reports, which may be due to differences in ascertainment or criteria for inclusion in cohorts, time to referral and diagnosis, data at presentation or during disease, or examination protocols.

suggested that rituximab provided a valuable steroid-sparing effect.⁴⁷ A few very severe cases have been successfully treated by autologous stem cell transplantation.⁴⁸

Long-term outcome of JDM in the modern era is unknown. The high mortality rate experienced before the use of DMARDs has improved, with current mortality estimated at 1% to 2% of cases. However, over time, new features of JDM can develop if disease is not fully controlled and cause serious morbidity and disability, including ulcerations, calcinosis, and contractures. When widespread, the severe "exoskeleton" form of calcinosis in JDM is highly disabling (Fig. 105.4). In a long-term study of 65 patients, 35% were still receiving medication and 40% still had rash at a median follow-up of 7 years; despite this, educational and vocational achievements were high.⁴⁹ Little is known about long-term cardiovascular risk in JDM; as with JSLE there is concern that this will prove to be a serious risk in patients with long-term inflammatory activity. In addition to disease burden, treatment of JDM generates morbidity through adverse effects, in particular from corticosteroids, including osteoporosis, weight gain, and growth retardation; these need to be set against growth inhibition and osteoporosis caused by active inflammatory disease itself. Long-term immune effects of biologic agents such as TNF blockade are not yet known, but careful screening for malignancy is mandatory.

Fig. 105.4 Calcification in juvenile dermatomyositis. (a) Calcinotic lesions on the forearm. (b) Extensive calcification in subcutaneous tissues of the legs seen on a plain radiograph.

JDM is a complex multifactorial disease whose management requires participation of a wide range of specialists over many years. Improved recognition to aid rapid diagnosis, as well as collaborative international sharing of data and a protocol-driven approach to treatment, should ultimately lead to more individualized treatment choices and improved outcomes.

SCLERODERMA

Scleroderma is a rare disorder in which the skin becomes thickened and hard. Scleroderma is divided into two forms: localized scleroderma and systemic sclerosis (SSc). Unlike in adults, localized scleroderma is the most common form in children. Recognition is often late. Scleroderma affects skin, subcutaneous tissues, and underlying muscle or bone. In SSc, the disease involves internal organs and is often preceded by Raynaud phenomenon.

Epidemiology

A British Paediatric Surveillance Unit survey was undertaken to establish the incidence of newly diagnosed childhood scleroderma in the United Kingdom.⁵⁰ Pediatricians and dermatologists reported 94 confirmed cases over 2 years—87 cases of localized scleroderma and 7 of SSc—which gives an estimated annual incidence of 3.4 per million for localized scleroderma (of which 2.5 per million were linear disease) and 0.27 per million for SSc. The localized cases occurred mostly in Europeans (87%), most were linear (68%), and a third of patients had lesions affecting the face and head.

Etiopathogenesis

The cause of scleroderma is unknown. Initiating factors are thought to be multifactorial: environmental triggers acting on a genetically susceptible individual. The hallmark of the disease is increased fibrosis, leading to thickened, hardened skin. There is increased deposition of collagen type I and II, which are synthesized by skin fibroblasts. This may be preceded by endothelial cell injury causing activation of perivascular fibroblasts, which leads to inflammation and tissue edema. Early lesions of the skin can look swollen and red, with a "woody" feel to the subcutaneous tissues. Later on, the fibrotic skin becomes relatively avascular and tight. In SSc, the inflammation and progressive fibrosis are most obvious in the skin but can also affect the

gastrointestinal, respiratory, renal, cardiovascular, and genitourinary systems. Vascular alterations show a predilection for the small arteries and arterioles, with vascular dysfunction as one of the earliest symptoms seen; Raynaud phenomenon occurs in 95% of adults and 75% of children.⁵¹

Clinical presentation

Localized scleroderma

Raynaud phenomenon is uncommon in localized scleroderma (12 of 750 patients in one study).⁵² Localized scleroderma is subdivided into morphea and linear scleroderma. In morphea, oval patches of thickened skin are seen (which can be pigmented), usually on the trunk (rarely on the digits). Linear scleroderma is the most common form seen in children. Thickened bands of skin can follow a dermatomal pattern, affecting the legs, arms, or face. The underlying tissues are often affected, which leads to functional and cosmetic problems. Linear scleroderma of the face is unilateral and may start in the midline, in which case it is called *en coup de sabre*. Localized scleroderma rarely evolves into SSc (1 of 750 cases⁵²).

Systemic sclerosis

SSc is very rare in children. It is divided into limited cutaneous SSc, in which the sclerosis is limited to the distal limbs (below the wrist or ankle) and the face; and diffuse cutaneous SSc, in which the sclerosis also involves the proximal limbs and the trunk. New classification criteria for juvenile SSc have been proposed. As with adult disease, the major criterion is skin thickening, with several minor criteria. The juvenile classification specifies that one major and two minor criteria must be met, whereas the adult classification specifies one major or two minor criteria (Box 105.1). SSc appears to be less severe in children, showing less visceral involvement and better long-term outcome, with renal crises reported in only 1 of 153 patients.⁵¹ Scleroderma can occur as an overlap syndrome with SLE, dermatomyositis, or juvenile idiopathic arthritis; however, patients with those disorders were excluded from these studies.

Management

Treatment is aimed at controlling inflammation; oral corticosteroids are commonly used,⁵¹ although care must be taken in SSc because corticosteroids can precipitate a renal crisis (seen in adult SSc). Second-line

BOX 105.1 PROPOSED CRITERIA FOR JUVENILE SYSTEMIC SCLEROSIS

Major criterion

Skin thickening/tightening/induration of the fingers proximal to the metacarpophalangeal or metatarsophalangeal joints

Minor criteria

Two of the following:

- Raynaud phenomenon
- Sclerodactyly
- Digital skin pitting/ulcers
- Nail-fold capillary abnormalities
- Dysphagia
- Gastroesophageal reflux
- Cardiac arrhythmias
- Cardiac failure
- Pulmonary fibrosis
- Reduced diffusion factor
- Pulmonary hypertension
- Renal crisis
- Hypertension
- Neuropathy
- Carpal tunnel syndrome
- Arthritis
- Myositis
- Tendon friction rubs
- Serologic autoantibodies such as anti-Scl-70

treatments include methotrexate, cyclophosphamide, D-penicillamine (although less since 1998), and mycophenolate mofetil. Vasodilators such as calcium channel blockers are used for Raynaud phenomenon and can help digital ulceration. Iloprost and bosentan are used for severe Raynaud phenomenon and pulmonary arterial hypertension. Physical therapy is important to maintain muscle strength (to counteract skin tightness) and to prevent restriction of movement. Many patients need psychological intervention because of the cosmetic problems, and once the disease is inactive, plastic surgery can be helpful.

Rehabilitation and psychosocial issues in juvenile idiopathic arthritis

■ SABRINA CAVALLO ■ DEBBIE FELDMAN

- Rehabilitation for children with juvenile idiopathic arthritis (JIA) requires a multidisciplinary team approach focused on promoting maximal independent function and participation in activities of daily living, school, work, and leisure.
- Assessment in JIA addresses disease impact in terms of impairment, function, and involvement in life situations, as well as quality of life.
- Rehabilitative interventions use thermal and electrical modalities, therapeutic exercise, splinting and casting techniques, motor skill development, and gait and fitness training to help improve mobility and strength and to limit pain.
- Adaptive strategies and specialized equipment may be needed to favor maximal function at home, at school, and in the community. The presence of JIA has long-term physical and psychosocial implications felt well into adulthood.
- The psychosocial stresses can be addressed through education, self-management courses, counseling, camp experiences, and family retreats.

INTRODUCTION

Juvenile idiopathic arthritis (JIA) is a complex disease that requires an interdisciplinary approach to treatment. Among the health care professionals typically caring for children with JIA are the pediatric rheumatologist, nurse, physical therapist, occupational therapist, and social worker. Other specialists such as orthopedic surgeons, ophthalmologists, and psychologists may also be consulted.

Rehabilitation professionals such as occupational therapists and physical therapists favor a family-centered approach in which child and parent may be involved in shaping meaningful treatment plans.¹ The goals of rehabilitation extend from improving adjustment to the physical limitations caused by the disease, to favoring functional abilities through daily exercises and adaptive equipment, to promoting the child's participation in life roles needed for proper development, well-being, and psychosocial integration.

In the following the authors have chosen to use the International Classification of Functioning, Disability, and Health (ICF),² which provides health care professionals with a conceptual framework for the description of functioning and disability, and is easily applicable to children with JIA.

In this chapter, JIA is described in terms of (1) impairment, which refers to the loss of body function or structure; (2) limitation in functioning, which refers to the difficulty an individual may experience in executing a particular activity; and (3) restriction in participation, which refers to the problems an individual may experience in involvement in life situations.^{2,3} The chapter first describes each of these disease components, then the measures most frequently used to assess them, and finally the evidence-based research supporting different interventions in rehabilitation.

IMPACTS

Children and adolescents with JIA often have chronic pain, joint tenderness and swelling, stiffness, decreased range of motion, joint deformity, decreased

muscle strength, poor cardiovascular endurance, increased fatigue, and headaches.⁴

Pain

Most children with JIA experience pain that fluctuates with changes in disease status. Sherry and associates showed that 86% of children with arthritis reported pain during routine clinical checkups when visiting their pediatric rheumatologist.⁵ Schanberg and coworkers⁶ found that the 41 children aged 8 to 18 years with polyarticular juvenile arthritis followed daily for 2 months reported pain on 73% of days. On average, participants rated their pain as mild to moderate, with 31% of children indicating they had severe pain.⁶

In response to articular pain, many children with JIA avoid tasks and activities that may be painful, which often leads to muscle and cardiovascular deconditioning.^{7,8} In the presence of regular inflammation, thresholds for afferent nociceptive fibers are decreased to below normal, which may result in higher-intensity and persisting pain that limits simple daily activities.⁹

Structural damage

In juvenile arthritis the number and symmetry of joint involvement differ depending on the different disease categories (oligoarthritis, polyarthritis, or systemic arthritis). Although any joint may be affected, it is the large joints that are most frequently involved. Joint involvement begins with swelling, stress pain at end of range, stiffness, and limited range of motion. The child may also have an enlarged joint caused by increased blood flow to the inflamed tissues.¹⁰ The acute and active phase of the disease is often characterized by morning stiffness, which may result in transient but significant range-of-motion loss.¹⁰

During the acute phase of active disease, intraarticular pressure is increased owing to inflammation. The enlargement of the articular capsule from increased synovial fluid causes stretching of the periarticular tissues. In response to this, to seek relief from pain, patients flex the involved joint, be it the wrist, elbow, or knee, which reduces the intraarticular pressure.¹¹ However, the long-term flexed position can shorten the flexor tendons and muscles, causing contractures and possibly deformity of the involved joints as well as malalignment of the adjoining bones (e.g., malalignment of the fingers when the wrist is involved).

Hand and wrist

Small-joint involvement of the hands is seen mostly in children with polyarticular arthritis. Joint involvement of the hand can range from a single joint to symmetric bilateral involvement. Clinical manifestations of arthritis in the hand include joint swelling, tenosynovitis, dactylitis, loss of range of motion, flexion contractures, joint deformities, and malalignment.⁴ In JIA, the wrist, metacarpophalangeal joints, and proximal interphalangeal joints can be involved. In a cross-sectional study of children with polyarticular JIA, abnormalities of the wrist related to periarticular osteoporosis, osteophytosis, narrowing of the joint space, and growth disturbances of the epiphysis were found in 21 of 23 children.¹¹ Malalignment of the wrist characterized by ulnar deviation and/or subluxation of certain carpal bones is a common deformity in children with JIA. The smaller joints of the hand are also vulnerable to deformity and loss of mobility, such as boutonnière deformities, flexion contractures, and swan neck deformities.¹²

Lower extremities

Children with JIA may also have a significant decrease in muscle strength.^{13,14} Broström and colleagues¹³ showed that young girls diagnosed with JIA who had active disease and lower-extremity involvement had weaker plantar flexor and dorsiflexor muscles than their age-matched peers. Klepper⁸ described children with JIA as having greater limitations in aerobic fitness and muscle strength compared with healthy children, presumably caused by decreased physical activity secondary to disease symptoms.

In addition to limited range of motion, children with JIA may be at risk of other musculoskeletal sequelae, such as leg-length and thigh circumference discrepancy.^{15,16} Clinical consequences of this may manifest as growth delays and premature stunting of the long bones, as well as the small bones of the hands.^{15,16} The reasons for the discrepancy in thigh circumference may be related to disuse or decreased load bearing of the leg due to capsular (or articular) damage, which could cause atrophy of the quadriceps of the involved leg.^{15,16}

Bone mineralization

Children with arthritis are at greater risk of developing osteopenia, that is, bone mineral density that is lower than expected for their age. Disease duration and severity, subtype of JIA (children with polyarthritis are at greater risk), use of corticosteroid treatment, growth retardation and limited physical activity may contribute to this risk.¹⁷ Other factors that may cause low bone mineral density are limited sun exposure, inadequate dietary intake of calcium and vitamin D, and low body mass (weight). Osteopenia can interfere with skeletal maturation and normal growth.¹⁸

Limitations in daily living

The impairments just described have an impact on function in everyday living and may require children to be dependent on family members for many of their activities of daily living, such as self-care and dressing.¹⁹ Children with JIA may have limited dexterity, which can limit their participation in writing activities and other school activities necessary for their development and social integration. Also, certain activities of daily living such as managing small fasteners and utensils may be hindered by finger joint tenderness and range-of-motion limitations. One in five adolescents rated twisting off a bottle or jar top, even if already loosened, and opening soft drink cans as the most problematic daily activities related to fine motor skills.⁴ Other problematic activities for older adolescents were pulling socks up, tying shoelaces, and putting on shoes.⁴ Ability to perform gross motor tasks, such as kneeling or sitting on heels for several minutes, standing for half an hour, and running two blocks, were also reported as limited.⁴ Younger adolescents (14-year-olds) reported problems participating in physical education classes and playing a favorite sport, with boys reporting this more often than girls.⁴ Some adolescents reported that driving was also a problem.⁴

Just over 40% of those diagnosed with JIA report persisting limitations well into adulthood, often as a result of joint deformity and destruction, and osteopenia.²⁰ They often have pain, reduced mobility, and difficulty with daily living.²⁰

PSYCHOSOCIAL IMPLICATIONS

Participation is defined by the World Health Organization as “the involvement of the person in life situations, which is influenced by both intrinsic and environmental factors.”² In children with JIA, increased daily symptoms of pain, stiffness, and fatigue were significant predictors of reduced participation in school and social activities.⁶ It has been shown that if participation remains limited on a long-term basis, children and adolescents may not have enough social contacts with peers, may be less able to make friends, may experience greater social isolation, and may be at greater risk of depression.²¹

Childhood

Children with JIA may also experience decreased participation in play due to pain and stiffness.²² Nevertheless, these children, with support from their families as well as community and health care professionals, may participate in activities with friends either by acting as spectators or by adapting the activity to suit their needs (e.g., walking instead of running).²² Unfortunately, when symptoms are significant children may retreat from certain activities, which affects not only their physical endurance but also their social integration.²²

Children may have to face being scrutinized by their peers in school because of their orthotics and their poor performance in writing activities,

and having to explain their disease to peers and teachers.²³ A qualitative study by Guell²³ explored the impact of JIA on the child's everyday life. Children reported adopting different management techniques to overcome the painful symptoms associated with their disease and to participate as fully as possible, albeit with limitations, in social and school activities.²³ Guell reviewed the notion of disease normalization, in which children and parents aspire for the child to have a normal life and eventually become a productive member of society.²³ Psychosocial issues (e.g., emotional distress, family functioning, mood, stress, coping with pain) can impact a child's participation in school and social activities. Although the global self-esteem of Dutch children with chronic juvenile arthritis did not differ from that of their healthy counterparts, they reported lower competency in athletics, possibly owing to the decreased opportunity to participate in sports compared with their healthy counterparts.¹⁹ Nevertheless, they still reported as many spontaneous social interactions as other children without JIA.¹⁹ With respect to body image, children with polyarticular juvenile chronic arthritis tended to view themselves as thinner compared with their classmates. Children with JIA have been shown to be at increased risk of psychosocial problems in comparison with healthy children.^{4,24} The effects of JIA on the child are felt well into adolescence and adulthood.

Adolescence

In a study of 308 adolescents with JIA, 30% reported frustration and 23% reported depression.⁴ These difficulties were particularly problematic for older adolescents, with 39% reporting frustration as one of their biggest problems and 64% reporting depression. Adolescents with greater disease activity, worse pain, worse general health, and greater functional disability were those most likely to rate frustration as one of their main problems. Similarly, adolescents described depression as their greatest problem when they experienced greater disease activity, worse pain, worse general health, and greater functional disability. Other frequently rated psychological problems included “interacted poorly with brothers and sisters” (19%), “felt sad” (19%), and “argued a lot” (17%).⁴ Thus social functioning and psychosocial adjustment appear to be directly related to the level of disease disability,^{4,21} and those with active or severe disease are at greater risk of social isolation, possibly psychosocial maladjustment, and depression.²⁵

Adulthood

Adults with a history of juvenile rheumatoid arthritis who had greater physical disability had more psychological difficulties.²⁶ Thirty percent were unemployed and believed that their arthritis was the reason for this.²⁶ A study in the United Kingdom confirmed that despite having a higher educational level, adults who had JIA had higher than average rates of unemployment.²⁷ However, a German study reported that of their cohort of patients who had had JIA for longer than 15 years, most demonstrated good social integration and had a lower rate of unemployment than their age-matched peers.²⁸

It is important to emphasize that body structure and function, activity, and participation are strongly linked, so that significant limitations in joint mobility, increased swelling, and pain of involved joints limit execution of daily activities and can hinder participation in age-appropriate roles.

EVALUATION

The impairments that children living with JIA must contend with are assessed using different measures and tools. In addition to the routine evaluation by the rheumatologist to assess the number of affected joints and erythrocyte sedimentation rate to determine disease classification and status,²⁹ other information on the child's function and participation must be collected to obtain a complete overview of the child's health status. Although rehabilitation professionals can also identify painful joints, they hold a key role in quantifying physical limitations in terms of pain, range of motion, and strength, as well as function, health-related quality of life, and participation. Using specific instruments rehabilitation clinicians can help determine change, progression of status, and effects of pharmacologic and rehabilitation interventions.

Pain scales

Pain is a frequent presentation among children and youth with arthritis and is most commonly assessed with self-report scales (Table 106.1).

Range of motion and muscle strength

Joint pain often limits movements and affects muscle strength. Range of motion is measured using different-sized goniometers to accommodate

TABLE 106.1
Pediatric pain measures

Scale	Content/purpose	Age	Reliability	Validity
Pain intensity visual analogue scale (VAS) ³⁰⁻³⁷	Self-report pain intensity visual analogue scale. 100-mm horizontal line anchored with terms "no pain" at left and "worst pain possible" at right. Respondent makes vertical mark on line to indicate his or her level of pain.	3 yr to adult; proxy report recommended for those younger than 8 yr	Fair to moderate test-retest reliability*: $r = 0.41-0.58$ Fair to good interrater reliability: $r = 0.28-0.72$	Moderate to excellent concurrent validity: $r = 0.61-0.90$
Wong-Baker Faces Pain Rating Scale ³⁸	Self-report pain intensity faces scale. Six line-drawn faces with descriptive terms from "no hurt" to "hurts worse."	3-18 yr	Fair interrater reliability: $r = 0.26-0.37$	Moderate to good concurrent validity: $r = 0.67-0.73$
The Oucher ^{33,34,39,40}	Self-report pain intensity scale. Two vertical pain scales: (1) Six-color photographic faces scale for younger children. (2) Numerical rating scale of 0 ("no hurt") to 10 ("the biggest hurt you could ever have") available for older children (8-12 yr).	3-12 yr	Good to excellent test-retest reliability: Photographic scale: $r = 0.88-0.91$ Numerical scale: $r = 0.91-0.99$	Moderate to excellent concurrent validity: $r = 0.62-0.98$
Varni-Thompson Pediatric Pain Questionnaire (PPQ) ^{30,41,42}	Self-report and parent/physician proxy assessing pain intensity, location, sensation, and affective impact. Intensity scale anchored by terms "No hurting, no discomfort, no pain" and "hurting a whole lot, very uncomfortable, severe pain."	5-18 yr	Fair test-retest reliability: $r = 0.29-0.41$ Fair to good interrater: $r = 0.40-0.85$	VAS scores were predictive of disability estimates ($P < .05$) Poor to moderate convergent validity: $r = 0.27-0.68$ with disease status; $r = 0.06-0.45$ with psychological functioning

*The stability of the measures is dependent on how the child recalls the pain.
 r , correlation coefficient

specific joints, whereas muscle strength can be assessed with dynamometers, vigorimeters, or via manual muscle testing (Table 106.2). Irrespective of the method of measurement, therapists must be cautious when assessing strength so as not to cause further pain.

Although it is necessary to assess impairments in body structures, new literature proposes that in addition to functional evaluations, quality of life and participation must be included in the clinical examination to assess health status and improvement accurately.⁵⁴

Function, quality of life, and health status

Although a physical evaluation can give rehabilitation professionals a good overall impression of disease severity, it does not provide enough information to thoroughly estimate the effects of disease activity in terms of the child's function. It has therefore become customary to question patients and family members regarding the limitations experienced by the child during daily activities. Also, results from functional, quality-of-life, and health status measures may be more meaningful to parents than physical measurements. These various measures are described in Tables 106.3 and 106.4.

Very little is known regarding the standardized and systematic evaluation of participation in different spheres of life (academic, social, leisure, and vocational) in children with juvenile arthritis. Different approaches can be used to evaluate participation. Daily diaries give a qualitative view of the person's participation in activities related to school, sports, and social activities.²³ The Child Behavior Checklist, a nonspecific questionnaire, describes the child's social functioning.¹⁹

Standardized assessments of participation for children with JIA need to be developed. A standardized generic assessment of participation, the Children's Assessment of Participation and Enjoyment (CAPE), has been administered to children with JIA.⁶⁸ The CAPE is a 55-item questionnaire designed to examine how children and youth participate in everyday activities outside of their school classes. The CAPE provides information about the following dimensions of participation: diversity (number of activities performed), intensity (frequency of participation measured as a function of the number of possible activities within a category), and enjoyment of activities. It also provides information about the context in which children and youth participate in these activities (e.g., with whom and where they participate).⁶⁹

Ideally, a disease-specific, standardized measure assessing participation related to communication, personal care, housing, mobility, fitness and nutrition, responsibility, recreation, education, community life, interpersonal relationships, attitudes, and beliefs toward involvement in different

activities may provide the health care professional with a comprehensive view of limitations in age-appropriate and meaningful life roles.

GOALS OF TREATMENT: EVIDENCE-BASED TREATMENT AND OUTCOME

Rehabilitation professionals have an important role to play in the care of children with JIA. Typical goals are to limit pain, prevent limitation, promote function, and improve range of motion in affected joints; maintain and improve muscle strength; increase and maintain endurance for activities of daily living; minimize the effects of inflammation; and promote normal growth, development, and participation in age-appropriate activities. Clinicians work closely with children to develop activity programs that suit their activity preferences, motivation, and interests in order to work toward the specified treatment goals. Examples of treatment interventions include home exercise programs; regular therapy sessions; inpatient hospital treatment; serial casting; night-time, serial, dynamic, or shoe splints; use of assistive devices for ambulation, school, and daily-living activities; joint protection; and the use of different therapeutic modalities, including heat, cold, ultrasound, and pool therapy (Table 106.5).

Physical therapists and occupational therapists also encourage and direct children with JIA to adopt healthier and more active lifestyles. In fact, there has been a shift in treatment strategies for children living with chronic conditions from recommending bed rest to now favoring the introduction of moderate exercise programs and promoting physical activity.⁷⁸ The danger that excessive inactivity will cause muscle weakness, joint contractures, and poor bone density is well recognized.⁷⁹⁻⁸¹ Table 106.6 describes the latest findings pertaining to more active treatment approaches. To promote better adherence to treatment, therapists review the importance and purpose of the different prescribed treatment regimens with parent and child.⁸⁷

Rehabilitation professionals may also be involved in treatments favoring the child's integration in school and the eventual workplace, as well as provision of relevant information pertaining to their arthritis, their treatment options, potential community services, and sources of support within the hospital and the community. They may need to consult with key players to help address contextual factors related to the family, school, and peers, including attitudes and perceptions impeding fulfillment of activities. To facilitate daily participation in school activities, health care professionals work with school officials (teacher, principal, physical education teacher)

TABLE 106.2

Tools and techniques for measuring range of motion and muscle strength

Measure	Description	Psychometric properties
Goniometer ⁴³⁻⁴⁵	Protractor with one axis that joins two arms (one stationary, the other movable). Angle of movement for a particular joint is measured by aligning goniometer arms with tested limb.	Excellent intrarater reliability: $r = 0.91-0.99$ Moderate to excellent interrater reliability: $r = 0.58-0.97$ Concurrent validity is established*
Paediatric Escola Paulista de Medicina Range of Motion Scale ⁴⁶	Range-of-motion scale assessing 10 movements: cervical spine rotation, shoulder abduction, wrist flexion and extension, thumb flexion (metacarpophalangeal), hip internal and external rotation, knee extension, and ankle dorsiflexion and plantar flexion. Four-point Likert scale (0 [no limitation] to 3 [severe limitation]). Final score is sum of mean scores for individual movements divided by 10.	Excellent test-retest reliability: $r = 0.96$ Excellent interrater reliability: $r = 0.98$ Moderate construct validity: $r = 0.55-0.65$
Jamar Hydraulic Hand Dynamometer ⁴⁷⁻⁵¹	Isometric grip strength is measured by asking participant to squeeze dynamometer handle. Maximal strength is recorded. During testing, patient sits with shoulders adducted and neutrally rotated, elbow flexed at 90 degrees, forearm in neutral position, and wrist between 0 and 30 degrees of dorsiflexion and between 0 and 15 degrees of ulnar deviation. Handle positions can be changed to accommodate child's hand size.	Excellent intrarater reliability: ICC = 0.90-0.97 Good to excellent interrater reliability: ICC = 0.80-0.95
Martin-type squeeze dynamometer-vigorimeter ⁵¹	Dynamic movement grip strength is measured by asking patient to apply pressure by squeezing a rubber bulb. Maximum force of the squeeze is registered on analogue dial. Various sizes are available to accommodate child's hand size.	Excellent intrarater reliability: ICC = 0.97 Excellent interrater reliability: ICC = 0.89-0.92 Concurrent validity ($r_s = -0.45$) with CHAQ's disability score
Hand-held dynamometer ⁵¹	Isometric force is measured by asking patient to push maximally against plate and piston of hand-held dynamometer with the muscle group being tested. Test limb is in a position not affected by gravity.	Excellent intrarater reliability: ICC = 0.92-0.97 Good to excellent interrater reliability: ICC = 0.80-0.93 Concurrent validity is established.
Pinch meter ^{48,49,51,52}	Pinch strength is measured for all pinch tests, that is, tip to tip, key, and palmar. Patient is simply asked to squeeze pinch gauge and maximal strength is recorded.	Excellent intrarater reliability: ICC = 0.92-0.97 Good to excellent interrater reliability: ICC = 0.80-0.95 Concurrent validity ($r_s = -0.33$) with CHAQ disability score
Manual muscle testing ⁵³	Isometric force is measured by asking patient to push maximally against examiner's hands with muscle group being tested. Test limb is in a position not affected by gravity. Both 0-5 point and 0-10 point scales have been used in clinical setting.	Excellent internal reliability: $r_s = 0.90-0.95$ Good internal consistency: ICC = 0.70-0.76 Moderate construct validity: $r_s = 0.47-0.70$

*The low measurement variability between goniometers supports concurrent validity, in that it would be unlikely that all three tools assessed measure range of motion inaccurately in the same way. Strong inter-rater reliability supports the goniometer as a measure of joint range of motion.

CHAQ, Childhood Health Assessment Questionnaire; ICC, intraclass correlation coefficient; r , correlation coefficient; r_s , Spearman's rank correlation coefficient.

TABLE 106.3

Pediatric functional measures used in juvenile idiopathic arthritis

Scale	Purpose/content	Administration	Time required	Scoring	Interpretation	Reliability	Validity
JAFAR ⁵⁵	Measures physical function by assessing child's ability to independently perform the activity in the past week. Twenty-three activities of daily function are included.	Parent proxy report and child self-report (ages 7-18 yr)	10-15 min	3-point scale (0 = all the time, 1 = some of the time, 2 = almost never). Total scores range from 0 to 46.	Higher scores indicate worse function.	Excellent internal consistency: parent report, Cronbach's $\alpha = 0.93$; child report, Cronbach's $\alpha = 0.85$	Good construct validity: $r = 0.69-0.75$
JAFAS ⁵⁶	Measures performance in completing 10 basic daily tasks.	Administered by physiotherapist or occupational therapist using simple equipment in clinical setting (ages 7-18 yr)	10 min	Participant performs 10 activities for which completion time is compared with a standard "criterion" time. Scores range from 0 to 20.	Lower scores indicate better function.	Good internal consistency: Cronbach's $\alpha = 0.85$	Fair to moderate convergent validity: $r = 0.32-0.59$
CHAQ ⁵⁷	Measures functional status for 30 activities in eight different domains (dressing and grooming, arising, eating, walking, hygiene, reach, grip, activities).	Parent proxy report (ages 1-18 yr) and child self-report (ages 8-18 yr)	10-15 min	Participant reports level of activity limitation. Total scores range from 0 (no limitation) to 3 (maximal limitation).	Lower scores indicate better function.	Excellent internal consistency: Cronbach's $\alpha = 0.94$ Good test-retest reliability: ICC = 0.8	Moderate to good construct validity: Kendall's tau-b = 0.54-0.77
JASI ^{58,59}	Part I: Measures activities of daily living and functional mobility; 100 functional items divided into five groups that include self-care, domestic, mobility, school, and extracurricular. Part II: Participants identify up to five tasks that are most problematic and these are reassessed at follow-up.	Child self-report (ages 8-18 yr)	45 min	Seven-point Likert scale of difficulty in performing tasks.	Higher scores indicate better function.	Part I: Excellent test-retest reliability: ICC ≥ 0.95 Part II: Moderate test-retest reliability: $\kappa = 0.57$	Moderate construct validity: $r > 0.50$

CHAQ, Child Health Assessment Questionnaire; JAFAR, Juvenile Arthritis Functional Assessment Report; JAFAS, Juvenile Arthritis Functional Assessment Scale; JASI, Juvenile Arthritis Status Index; ICC, intraclass correlation coefficient; Kendall's tau-b, Kendall's tau-b; Kendall's tau-b, Kendall's tau-b; κ , kappa statistic.

TABLE 106.4
Pediatric quality-of-life and general health measures used in juvenile idiopathic arthritis

Scale	Content/purpose	Administration	Time required	Scoring	Interpretation	Reliability	Validity
JAAQ ^{65,62}	Measures disease-specific health-related quality of life. Includes 74 items: gross motor function (17 items), fine motor function (16 items), psychosocial function (22 items), and general symptoms (19 items). Response options/scale.	Self-report	~20 min	Each item uses seven-point ordinal scale ranging from 1 (none of the time) to 7 (all of the time).	Higher score indicates poorer health-related quality of life.	Good internal consistency	Face, content, and construct validity established.
PedsQL ⁶³ (Core and Rheumatology modules)	Measures health-related quality of life in healthy children and adolescents and those with acute and chronic health conditions. Core module: 23-item scale measuring physical function. Items are distributed among four subcategories: emotional, social, and school functioning, physical functioning. Rheumatology module: 22-item scale. Items are distributed among four categories: pain and hurt, daily activities, treatment, worry and communication.	Parent proxy report and child (ages 5-7 and 8-12 yr) and teenager (ages 13-18 yr) self-reports	5 min	0-4 item scale for raw scores is reversed to a 0-100 scale.	Higher scores indicate better health-related quality of life.	Core module: Good to excellent internal consistency for child self-report: Cronbach's $\alpha = 0.86-0.91$ Internal consistency for parent proxy: Cronbach's $\alpha = 0.89-0.93$ Rheumatology module: Fair to excellent internal consistency for child self-report: Cronbach's $\alpha = 0.75-0.86$ Internal consistency for parent proxy: Cronbach's $\alpha = 0.0.82-0.91$	Construct validity established: PedsQL distinguished between healthy children and children with rheumatic diseases as a group.
CHQ-PF50 ^{64,65}	Measures parent-perceived functional health status. Fifty items divided into 13 single and multi-item scales: general health perceptions; physical functioning; general behavior; mental health; emotional or time impact on the parent; family cohesion; change in health; bodily pain; limitations in school, work, and activities with friends due to physical problems and emotional and behavioral difficulties; behavior; mental health and self-esteem; and limitations in family.	Parent proxy report (ages 5-18 yr)	10-15 min	Multi-item scales are transformed to range of 0-100, with 0 indicating poor health and 100 indicating excellent health.	Higher scores indicate better function.	Excellent internal consistency for parent report: Cronbach's $\alpha = 0.93$ Good internal consistency for child report: Cronbach's $\alpha = 0.85$	Construct validity established between child and proxy report ($r = 0.75$) as well as with the JAFAS ($r = 0.69$).
CAHP ^{66,67}	Attempts to measure a wide range of health statuses in disease-specific and generic disorders, including behavior, well-being, self-esteem, impact of disease on the family, and functioning in school.	Parent proxy report and child self-report (ages 7-18 yr)	15 min	Unknown.	Unknown.	Reliability coefficient* = 0.84-0.97	Internal and discriminant validity partially established.

CAHP, Childhood Arthritis Health Profile; CHQ-PF50, Child Health Questionnaire Parent Form 50 items; JAAQ, Juvenile Arthritis Quality of Life Questionnaire; PedsQL, Pediatric Quality of Life Questionnaire.

*Reliability coefficient was not specified.

TABLE 106.5

Therapeutic interventions

Type	Brief description	Therapeutic goal
Assistive devices	- Ambulation (cane, walker, wheelchair) - School writing aid (pencil grip) - Daily living (shoehorn, reacher, etc.)	- Promote independence and function in mobility, school activities, and daily living. - Limit pain.
Splinting ^{70*}		
Hand and wrist ^{11,71,72}	- Cock-up splint (Fig. 106.1) maintains wrist in pronation and 15-20 degrees of extension supported by forearm-based splint extending to middle of palm. - Hand-resting splint commonly worn at rest (Fig. 106.2) maintains wrist in pronation and 15-20 degrees of extension, as well as supporting fingers in slight flexion.	- Limits forced flexed position of the wrist and fingers.¹¹ - Limits pain. - May prevent further contractures. - Decreases ulnar deviation (joint deformity and misalignment).⁷⁴ - May improve grip strength and dexterity and decrease joint swelling.⁷⁵ - May increase function in fine motor tasks.
Elbow ¹¹	Splint is molded to fit anterior portion of arm and extends distally from elbow. Maintains elbow in maximal extension as tolerated by patient and is commonly worn at rest.	- Limits forced flexed position of elbow.¹¹ - May prevent further contractures.
Knee ^{11,73}	Splint is molded to fit behind child's knee to ensure maximal stretching in extension. Maintains knee in maximum extension as tolerated by patient and is commonly worn at rest (Fig. 106.3).	- Limits forced flexed position of the knee. - May prevent further contractures. - May help improve both passive and active range of motion.
Foot ⁷⁴	Custom-made semi-rigid foot orthotics with shock absorbing posts are fit in patient's shoe.	- Limits pain. - Improves speed of ambulation. - Reduces limitations.
Stretching ⁷⁵	Stretching should be maintained for 10 sec, released for 20 sec, and repeated 5-10 times in each session performed twice daily.	- May help improve passive range of motion. - May help prevent further contractures.
Therapeutic modalities ⁷⁵	- Heat is commonly applied for 15-30 min; however, heat should not be used on swollen active joints. - Cold may be applied for 20 min or according to child's tolerance. Cold therapy has an analgesic and vasoconstriction effect and is especially helpful for acute pain. - Ultrasound therapy. - Pool therapy.	- Relieve pain. - Relieve muscle tightness. - May decrease pain.
Massage therapy ⁷⁶	A 15-min massage comprised of two standardized phases given in a progressive sequence in both supine and prone positions, similar to that performed by massage therapists.	- Decreases anxiety levels of both child and parent. - Decreases child's levels of cortisol stress hormone.
Cognitive-behavioral approach by Walco ⁷⁷	- Teaches progressive muscle relaxation and meditation breathing exercises. - Instructs on the use of guided imagery.	Promotes pain management by helping to distract from pain.

*Splints are used in conjunction with regular stretching and pharmacologic treatment to promote treatment efficacy.

Fig. 106.1 A cock-up splint for night use supports the wrist in extension.

Fig. 106.2 A hand-resting splint for night use maintains the wrist in extension and fingers in slight flexion (safe position).

Fig. 106.3 A knee-extension splint is used to help counteract the effects of joint contractures.

TABLE 106.6
Exercise and physical activity interventions in juvenile idiopathic arthritis (JIA)

Intervention	Participants (age)	Study design	Outcomes
15-wk aquatic exercise program ⁸²	25 children with JIA (5-12 yr)	Pilot study (prospective)	Increase in health-related quality of life (general symptoms). No significant positive effects on functional ability, joint status, or physical fitness.
20-wk aquatic training program ⁸³	54 children with JIA (5-13 yr)	Randomized controlled trial	55% decrease in number of swollen and tender joints; results only tended toward statistical significance. No significant positive effects on functional ability, quality of life, and physical fitness.
12-wk circuit-training program including land- and water-based exercises ⁸⁴	9 children with JIA (8-11 yr)	Pilot study (prospective)	Increase in physical function, quality of life, fitness, and energy levels.
Vigorous or gentle exercise over 12-wk period ⁸⁵	80 children with JIA (8-16 yr)	Randomized controlled trial	Increase in physical function for both study groups equally. Better adherence in low-intensity group.
12-wk program including jumping, weight-bearing and muscle-strengthening exercises ⁸⁶	54 children and adolescents with JIA (9-21 yr)	Randomized controlled trial	Increase in bone mineral density. Increase in physical exercise in leisure time at 12-wk follow-up.

Fig. 106.4 Building up the pencil with a specialized grip helps alleviate symptoms of arthritis in fingers when writing.

Fig. 106.5 A thumb-splint can aid in stabilizing the child's thumb during writing activities.

to increase awareness of arthritis, as well as adapt the environment and curriculum as needed.

Occupational therapists may recommend adapted writing tools (Figs. 106.4 and 106.5) and workstations, as well as providing more time for completion of writing tasks and possibly the use of a keyboard to facilitate writing and tabletop activities and to limit pain in involved joints (fingers, wrist, neck).⁸⁸ The child's classes may also be moved to the first floor or the child may be granted access to the school elevator to facilitate mobility if lower extremity joints are affected. To assist the child's transition into adulthood, vocational rehabilitation can be provided and may have an impact on completion of higher levels of education and employment in patients with JIA.^{89,90}

The provision of health-related information through Web-based forums may facilitate accessibility of information regarding disease symptoms, treatment, and self-management techniques, as well as supplying links to community support.⁹¹ This information may help facilitate the child's transition to adult care. Furthermore, organized information programs or workshops provided through community or hospital-based services may favor parental coping, increase understanding of the disease's clinical and treatment implications, and improve the family's involvement in decision-making regarding the child's care and treatment management.⁹²⁻⁹⁴

CONCLUSION

This chapter has addressed aspects of the child's disability related to physical impairments and limitations in activities, and has explored the implications of disease on the child's involvement in social, school-based, and recreational activities. Much research has been completed on the assessment and treatment of biologic and musculoskeletal disease presentations; however, further studies are needed to assess the effectiveness of interventions favoring the child's participation in various age-appropriate roles. An interdisciplinary team approach, together with parent and child, is needed to help the child achieve optimal fulfillment in physical, academic, and social activities to favor health and well-being.

INFECTION-RELATED
RHEUMATIC DISEASES

107

Infectious arthritis I:
bacterial arthritis

■ ALEJANDRO BALSA ■ EMILIO MARTÍN-MOLA

- Staphylococci are the most common bacteria causing joint and osseous infections, and methicillin-resistant *Staphylococcus aureus* strains are an emerging problem.
- The risk of septic arthritis is increased in patients with rheumatoid arthritis, joint prosthesis, and immunocompromise; in the elderly; and in patients receiving anti-tumor necrosis factor therapy.
- Factors that predispose to prosthetic joint infection are older age, poor nutritional status, coexistence of joint diseases, obesity, diabetes, malignancy, remote infection, prior native joint infection, prosthesis revision surgery, and superficial surgical site infection.
- There is little evidence to guide the choice and duration of antibiotic treatment. The choice of antibiotics currently is based on the risk factors present and the organism considered most likely to be involved.
- The incidence of gonococcal arthritis has decreased, but it is the most common type of septic arthritis in patients younger than 30 years of age.
- The emergence of penicillinase-produced strains of *Neisseria gonorrhoeae* has changed the recommendations for the treatment of disseminated gonococcal infection.
- Musculoskeletal symptoms may appear in the congenital, secondary, or tertiary phases of syphilis but are most common in the secondary stage.

INTRODUCTION

Joint and bone infections are true rheumatologic emergencies because they may cause serious morbidity, permanent disability, or even death. The introduction of antibiotics has changed this course, but only when the drugs are active against the invading microorganism and are administered early. This emphasizes the two most significant problems: early diagnosis and prompt and effective treatment.

SEPTIC ARTHRITIS AND OSTEOMYELITIS

Epidemiology
Septic arthritis

Septic arthritis is an uncommon disease, with few studies large enough to provide robust estimates of incidence. The estimated incidence of acute septic arthritis in industrialized countries varies from 2 to 6 per 100,000 people per year,^{1,2} with the highest incidence occurring in those younger than 15 and older than 55 years of age.³ Thus in children the incidence is between 5 and 12 per 100,000 per year⁴; it is rare in children younger than 3 months of age.³ In patients with rheumatoid arthritis or joint prostheses, the incidence increases to 30 to 60 per 100,000 per year.^{5,6}

Prognosis

The prognosis of bacterial arthritis has not improved significantly, despite the availability of better treatment. Irreversible loss of joint function develops in 25% to 50% of patients,^{1,7} and the outcome depends on the types of microorganisms involved, type of disease, patient age, presence of comorbidities, and length of delay in the start of treatment. Total mortality rates were directly attributed to septic arthritis in 2% to 10% of cases,⁸ with polyarticular septic arthritis having a high mortality rate.²

Osteomyelitis

The incidence of osteomyelitis has been estimated at 2.4 cases per 100,000, with the incidence increasing with increasing age.⁹ Open fractures can lead to osteomyelitis depending on the fracture type, extent of soft tissue injury, and degree of microbial contamination. The incidence of hematogenous vertebral osteomyelitis is 0.5 to 2.4 per 100,000, increases with age,¹⁰ and most often results from hematogenous seeding, direct inoculation during spinal surgery, or continuous spread from adjacent tissues.⁹

Microbiology
Septic arthritis

The main causative organisms of septic arthritis are listed in Table 107.1.¹¹ In all age groups except neonates, *Staphylococcus*, mainly *Staphylococcus aureus*, is the primary cause and is responsible for 37% to 56% of cases. Methicillin-resistant *S. aureus* (MRSA) is an emerging problem, accounting for 25% of all septic arthritis cases in one urban area.¹² Group A and B streptococci are the next most common causative bacteria, mainly in the elderly. This is especially true in patients with chronic diseases such as diabetes, cirrhosis, or neurologic diseases.¹³ Most coagulase-negative staphylococci cultured from joints are contaminants, but they can become true pathogens after surgical arthroscopies, multiple procedures, and placement of a joint prosthesis.⁸ The two most frequent gram-negative organisms are *Neisseria gonorrhoeae* and *Neisseria meningitidis*, which account for up to 20% of cases. Gram-negative organisms such as *Escherichia coli*, *Proteus mirabilis*, *Klebsiella*, and *Enterobacter* are seen infrequently and are more common in the elderly, in immunocompromised patients, and in intravenous drug abusers.¹⁴ Anaerobic organisms cause septic arthritis when there is a history of penetrating trauma. In intravenous drug abusers, *S. aureus* and gram-negative organisms are common along with more unusual microorganisms, including fungi.

Before immunization *Haemophilus influenzae* type b was a common cause of bacterial arthritis in children, but it is now rare. *Kingella kingae* is the most common gram-negative bacillus causing arthritis in children between 2 months and 5 years of age.¹⁵ Septic arthritis in infants younger than 2 months of age can be caused by *S. aureus*, *Streptococcus agalactiae*, or gram-negative enteric bacteria. *S. aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and *K. kingae* are the predominant organisms affecting children between 2 months and 5 years of age. Children older than 5 years are more likely to have arthritis caused by *S. aureus* and *S. pyogenes*.¹⁶ *S. aureus* is the microorganism most frequently responsible for septic bursitis.¹⁷

No causative organism is identified in 20% to 50% of patients, most likely owing to initiation of antibiotic therapy before specimens were obtained, inadequate culture techniques, the changing patterns of the organisms, or failure to collect appropriate samples.^{3,9}

Osteomyelitis

Hematogenous osteomyelitis is almost always a monomicrobial infection, with *S. aureus* being the most frequently identified microorganism (see Table 107.1).⁹ Coagulase-negative staphylococci, anaerobic gram-negative bacteria, and *Peptostreptococcus* species can also be isolated. In children, *S. aureus* is the most common causative organism, and recently MRSA has become an increasingly common cause. Group A β -hemolytic streptococci, *S. pyogenes*, and gram-negative enteric bacteria are infrequently causes. Effective immunization against *H. influenzae* has virtually eliminated this cause, and its place has been taken by *S. pneumoniae* and *K. kingae*.^{4,15} Posttraumatic osteomyelitis is often a polymicrobial infection.

Pathogenesis

Septic arthritis

For septic arthritis to develop, pathogens must enter the synovial joint (Fig. 107.1), which occurs via the bloodstream in the majority of cases because synovium is highly vascular and lacks a protective basement membrane.¹⁴ In very young children with osteomyelitis, medullary infection may spread

to the epiphysis and joint cavity through capillaries that cross the growth plate (Fig. 107.2). The periosteum is also thin and does not adhere tightly to the underlying bone, and infection can spread into the surrounding tissues or can arise from contiguous spread.⁴ Finally, pathogens may enter the joint by direct inoculation or penetrating trauma. The risk factors for development of septic arthritis are shown in Box 107.1.^{1,18} The presence of combinations of independent risk factors substantially increases the risk.¹⁸

Osteomyelitis

Hematogenous osteomyelitis is the most frequent type and primarily affects the metaphysis because the bacteria travel through vascular tunnels and adhere to the bone matrix. Animal models show that bone infection becomes

BOX 107.1 RISKS AND PREDISPOSITION FACTORS FOR THE DEVELOPMENT OF SEPTIC ARTHRITIS

- Rheumatoid arthritis
- Prosthetic joints
- Low socioeconomic status
- Advanced age (>80 years)
- Intravenous drug abuse
- Alcoholism
- Diabetes mellitus
- Intraarticular injection
- Skin infections, cutaneous ulcers

TABLE 107.1
Usual causative organisms of septic arthritis and osteomyelitis

Fungi	

Fig. 107.1 Bacteria can reach the joint via hematogenous spread or by contiguity from nearby infections, open trauma, or directly inoculated by invasive techniques.

Fig. 107.2 The development and course of osteomyelitis differ with age. In infants younger than 1 year of age the epiphysis is nourished by arteries penetrating through the physis, which allows development of the condition within the epiphysis. In children up to 15 years of age the infection is restricted to below the epiphysis because of interruption of the vessels.

more likely after trauma.¹ Infection of the vertebrae and intervertebral disks is typically hematogenous. Infection occurs via the segmental arterial circulation of the vertebrae and spreads by extension through the endplate into the disk or the lateral plane, which may lead to paravertebral abscesses. Most patients with hematogenous osteomyelitis have underlying chronic diseases.⁹

The virulence of the infecting organism, the size of the bacterial inoculum, and the resistance of the host determine whether infection occurs. The virulence of *S. aureus*, the most prevalent pathogen, depends on the relative inefficiency of innate host defenses when dealing with extracellular toxins and enzymes, components of the cell wall, bacterial DNA, and the expression of a capsule, which is a major determinant of virulence.¹⁹ The process of bacteria interacting with host tissues is highly dynamic and subject to modulation by the regulatory mechanisms of the bacteria, environmental factors, host defense mechanisms, and antibacterial therapy.

Clinical features

Septic arthritis

Septic arthritis usually presents as the abrupt onset of a hot, swollen, and painful joint, but significant delays may occur with low-virulence organisms, tuberculosis, and prosthesis infection. Mild fever is common, but up to 40% of individuals have high fever.⁶ The knee is the most common site in adults and the hip is most common in children, followed by the shoulder, wrist, and ankle.²⁰ Infections of cartilaginous joints is frequent in intravenous drug users.²¹ Patients with sacroiliac septic arthritis have buttock pain, fever, and pain on maneuvers that stress the sacroiliac joint. Infection of the pubic symphysis presents as fever, suprapubic and hip pain, and an antalgic gait. Septic sternoclavicular arthritis can be a result of infected central lines. Septic arthritis usually affects only one joint but is polyarticular in 10% to 20% when comorbid systemic diseases or overwhelming sepsis occurs.²² In children, the pattern of acute septic arthritis is similar to that in adults.⁴ Septic arthritis does not appear to occur more often in patients with human immunodeficiency virus (HIV) infection than in other patients except in patients with advanced HIV infection, who may develop septic arthritis caused by *S. aureus* or opportunistic organisms.²³ Clinical experience suggests that elderly patients are more likely than others with septic arthritis to be afebrile. There may be evidence of an associated skin, urinary tract, or respiratory tract infection, which should provide a clue to the likely infecting organism.

Risk of septic arthritis is increased in patients with rheumatoid arthritis, and *S. aureus* is the microorganism most frequently responsible. Data from the British registries has shown that the use of anti-tumor necrosis factor (TNF) therapy in rheumatoid arthritis is associated with a doubling in the risk of septic arthritis, and the risk did not differ significantly between the three anti-TNF agents. The risk was highest in the early months of therapy, and the patterns of reported organisms differed in the cohort receiving anti-TNF treatment. Prior joint replacement surgery was a risk factor for septic arthritis in all patients.²⁴

Long-bone osteomyelitis

Acute osteomyelitis usually produces pain at the affected site and fever. Young infants and toddlers are the most frequently affected and may show irritability and refusal to bear weight and/or to use an extremity (Fig. 107.3). In very young patients, subperiosteal spread may lead to septic arthritis or local symptoms, such as symptoms similar to those that occur when osteomyelitis arises from a contiguous focus of infection. Chronic osteomyelitis usually presents as persistent pain, low-grade fever, and drainage. Subacute Brodie abscess is a chronic form of osteomyelitis that can present without inflammatory local signs (Fig. 107.4).

Vertebral osteomyelitis

Patients with vertebral osteomyelitis usually experience an insidious onset of local pain and tenderness, with fever occurring in fewer than half of cases. The most common site is the lumbar spine (58%), followed by the thoracic spine (30%) and the cervical spine (11%); neurologic impairment, such as sensory loss, weakness, or radiculopathy, is reported in one third of cases.⁹ Vertebral osteomyelitis is in most cases a secondary complication of a distant infection with hematogenous seeding, and the symptoms may initially be dominated by manifestations of the primary infection. The differential diagnosis of back pain in a febrile patient includes a viral syndrome, pyelonephritis, and pancreatitis, among other causes.⁹

Prosthetic joint infection

The rate of infection after primary implantation of a joint prosthesis is approximately 1% for hip prostheses and 2% for knee prostheses, whereas the rate after revision surgery it is somewhat higher. Factors that predispose

Fig. 107.3 An acute osteomyelitis in the proximal metaphysis of the left humerus. The child is not willing to move the affected limb. The roseola is consistent with a *Salmonella* infection, which was confirmed by fecal cultures.

Fig. 107.4 Subacute osteomyelitis (Brodie abscess). The well-defined oval lucency in the distal tibia shows fading sclerosis along its margins in a pattern typical of a bone abscess. Note the small projection of the upper pole of the lesion pointing to the medial metaphysis, where a subtle periosteal reaction is beginning to form (arrow). This identifies the site where this lesion may ultimately drain.

to prosthetic joint infection are older age, poor nutritional status, coexistence of joint diseases, obesity, diabetes, malignancy, remote infection, prior native joint infection, prosthesis revision surgery, and superficial surgical site infection.²⁵ Early infections (less than 3 months after surgery) are caused mainly by *S. aureus*, *Streptococcus*, or gram-negative bacilli, and patients typically have fever, malaise, and local signs of wound infection. Delayed infection (3 to 24 months) is usually caused by less virulent bacteria, such as coagulase-negative staphylococci, and general symptoms are less impressive. Persistent pain is present and local signs may be absent. Late infection (longer than 2 years after surgery) is almost always due to hematogenous seeding, such as from the skin, a dental origin, or a urinary tract infection, and is characterized by sudden local pain and general symptoms.

Differentiation of aseptic loosening from infection is important, because the associated treatments differ (Fig. 107.5). There are no accepted criteria

Fig. 107.5 Periosteal reaction, scalloping, severe radiolucency at the interface, fistula through the bone, and severe bone resorption are illustrated. All of these changes can also be seen in mechanical loosening but do not progress as rapidly as in infection.

to diagnose prosthetic joint infection, although it is strongly suggested by the presence of at least one of the following: growth of an identical organism in at least two cultures of synovial fluid or periprosthetic tissue, purulent synovial effusion, presence of granulocytes on periprosthetic tissue, or presence of a sinus tract communication.²⁵ Radiographic findings such as radiolucency, osteolysis, and migration can be present in both infection and aseptic loosening, although changes progress faster in prosthetic joint infection. The usefulness of computed tomography and magnetic resonance imaging (MRI) is limited by artifacts. Radionuclide imaging is the procedure of choice when leukocyte and bone marrow imaging are combined and has an overall accuracy in the range of 88% to 98% (Fig. 107.6).²⁶ New techniques such as positron emission tomography with fluorine-18–labeled fluorodeoxyglucose are not capable of distinguishing aseptic loosening from prosthetic joint infection.²⁷ Treatment of prosthetic joint infection requires a three-stage procedure that includes removal of the infected prosthesis, a long course of systemic antimicrobial therapy, and eventually a new arthroplasty.

Septic bursitis

S. aureus is the microorganism most frequently responsible for septic bursitis.¹⁷ Septic bursitis is more frequent in males and in the olecranon bursa (Fig. 107.7). Risk factors are trauma, alcoholism, preexisting bursal disease, and diabetes, but an absence of risk factors is more common in non-*S. aureus* septic bursitis. The usual pattern is a painful bursa that is hot with swelling and erythema, typically with some evidence of cutaneous injury. Joint function is typically not affected except in cases of severe inflammation. White blood cell counts are typically not as high as in septic arthritis.²⁸

Investigations

A definitive diagnosis should require identification of bacteria either by Gram stain or by culture; however, the gold standard for diagnosis of septic arthritis is the level of clinical suspicion of an experienced

Fig. 107.6 A knee prosthesis 1 year after surgery in a patient with rheumatoid arthritis and severe pain at rest and on weight bearing. (a, b) The radiographs show no abnormalities and no radiolucency. (c) Technetium-99m–nanocolloid scintigraphy shows obvious increased uptake corresponding to the distal femur and proximal medial tibia. (d) The uptake with Indium-111–leukocyte scintigraphy was increased in a similar distribution.

Fig. 107.7 Bursitis symptoms are similar to those of arthritis, but a diagnostic puncture of the bursa containing purulent material in septic bursitis is easy to perform.

physician.²⁵ Clinical suspicion should prompt immediate synovial fluid aspiration by closed-needle aspiration, imaging guidance techniques, or surgical arthrotomy.

Laboratory features

Bacterial arthritis is part of the differential diagnosis of acute monoarthritis. No clinical or laboratory feature is specific for septic arthritis. A high synovial fluid white cell count increases the likelihood of a diagnosis of joint sepsis (Tables 107.2 and 107.3) and should be used in conjunction with clinical, imaging, and other laboratory findings.^{18,29} Infectious arthritis was diagnosed in 77% of patients with synovial white cell counts of more than 100,000/mm³, in 47% with counts in the range of 50,000 to 100,000/mm³, and in 5% with counts of less than 50,000/mm³. A majority of these infections were due to *S. aureus*, whereas infections associated with counts of less than 20,000/mm³ were associated with atypical organisms.³⁰

Synovial fluid glucose level is often depressed, although such values may also be observed in inflammatory diseases such as rheumatoid arthritis.⁸

Microbiologic testing

Prompt microscopic analysis and culture of synovial fluid are fundamental diagnostic tools in the evaluation of septic arthritis, enabling rapid diagnostic confirmation of both joint infection and microcrystalline arthritis.²⁶ In a review, synovial fluid Gram staining was found to yield positive results in only 50% of cases, and synovial fluid and blood cultures were positive for organisms in more than half of cases of nongonococcal bacterial arthritis.¹² One third of specimens from patients not receiving antibiotics and half of those from patients receiving antibiotics showed positive results on culture after inoculation of synovial fluid into blood culture bottles despite negative culture results when conventional solid media were used.³¹ However, a study of 94 synovial fluid cultures for 90 patients with acute joint effusions found no significant differences in the yield of positive culture results with the use of conventional agar plate culture, culture with lysis and centrifugation (Isolator) tubes, and broth-enriched blood culture bottles.²⁹ Blood culture results are positive in approximately 50% of cases in patients with suspected bacterial arthritis (even if fever is absent at the time of initial evaluation). Samples from other sites should be cultured if appropriate, including skin lesions, urine, or other suspected primary foci.

Inflammatory markers such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are commonly measured in the early evaluation of patients with septic arthritis; the significance of the levels of these markers is uncertain. Elevations of CRP are usually present, although the sensitivity of the ESR test in patients with septic arthritis is inconsistent.³²

New techniques have emerged for the detection of bacteria in biologic fluids. DNA-based techniques, hybridization probes, polymerase chain reaction–based detection, and protein-based detection by mass spectroscopy provide quick results, but their usefulness in clinical practice needs to be proved.³³

Imaging

Conventional radiography should always be the first imaging technique, although it lacks sensitivity and specificity, and abnormalities indicates that

TABLE 107.2
Likelihood of a diagnosis of joint sepsis depending on the number of white blood cells in synovial fluid

Synovial fluid white blood cell counts	Likelihood of a diagnosis of joint sepsis
Fewer than 25,000/mm ³	0.32
More than 25,000/mm ³	2.9
More than 50,000/mm ³	7.7
More than 100,000/mm ³	28

the infection has been present for at least 2 to 3 weeks. In septic arthritis, osteopenia and progressive destruction of the joint and subchondral bone occur. In osteomyelitis, the initial finding is osteopenia, followed by cortical destruction and potentially periosteal new bone formation. Subacute and chronic forms of osteomyelitis have different characteristics on imaging, because marginal sclerosis and areas of osteopenia may be seen that indicate areas of healing. The most specific finding in chronic osteomyelitis is a sequestrum, a fragment of dead bone surrounded by inflammatory tissue that appears radiographically as a focal area of sclerotic bone within an area of lucency. Ultrasonography is very sensitive in detecting joint effusion. Two- or three-phase scintigraphic scans have been shown to be sensitive and somewhat specific; however, in the presence of previous joint or bone damage, the specificity is significantly reduced.³⁴ Indium-111 labeling of leukocytes combined with the use of technetium-99m improves the sensitivity and specificity, and results are considered positive if an uptake of leukocytes without uptake of sulfur colloid is observed.²⁶ MRI with contrast is the most powerful imaging technique for the evaluation of musculoskeletal infections, with a sensitivity of almost 100% and a specificity higher than 75%³⁴ (Fig. 107.8). Acute and chronic osteomyelitis can be differentiated with MRI, because acute infections do not show a sharp zone of transition between normal and abnormal bone marrow and do not have cortical thickening or sequestrum (Fig. 107.9).

Differential diagnosis

The differential diagnoses for bacterial arthritis include gout, pseudogout, reactive arthritis, rheumatoid arthritis, viral arthritis, and Lyme disease, each of which can present with acute involvement of one or a few joints.

Management
Septic arthritis

No randomized controlled studies have evaluated antibiotic regimens for bacterial arthritis. The initial choice of antimicrobial regimen is based on coverage of the most likely organisms to cause infection in this setting, the Gram stain results, the clinical presentation, and case series. Treatment of septic arthritis includes admission to the hospital and daily removal of purulent synovial fluid. Needle aspiration, if possible, is preferable to

Fig. 107.8 Septic arthritis of the ankle complicated by osteomyelitis. (a) A sagittal T1-weighted spin-echo magnetic resonance image shows severe destruction of the subtalar joint with bone involvement. (b) Contrast-enhanced T1-weighted spin-echo magnetic resonance image shows generalized enhancement of both synovial and bone tissues and abscess formation into the talus and calcaneus.

Fig. 107.9 Osteomyelitis. Coronal contrast-enhanced T1-weighted spin-echo magnetic resonance image with fat suppression of first metacarpophalangeal joint. Note bone marrow edema with soft tissue and capsular thickening with gadolinium enhancement.

arthroscopic drainage or surgical drainage.³⁵ It is not necessary to immobilize the infected joint, although weight bearing should be avoided. The joint should be maintained in a functional position, and active exercises can be started when inflammation has substantially subsided.⁶

There is little evidence on which to base the choice and duration of antibiotic treatment, and there are no randomized clinical trials addressing this issue. The usual course of therapy is 2 weeks for infection with streptococci or gram-negative cocci, 3 weeks for staphylococcal infection, and 4 weeks for infection with pneumococci or gram-negative bacilli.⁶ A summary of suggested empirical antibiotic treatment based on different patients groups and a review of the literature is presented in Table 107.4.

TABLE 107.4

Suggested empirical treatment of suspected septic arthritis

Patient group	Antibiotic choice
Patients with no risk factors for atypical organisms	Flucloxacillin, 2 g qid IV. Local policy may be to add fusidic acid 500 mg tid PO, or gentamicin IV. If the patient is allergic to penicillin, clindamycin 450-600 mg qid or second- or third-generation cephalosporin may be administered.
Patients at high risk of gram-negative sepsis (elderly, frail, recurrent UTI, recent abdominal surgery)	Second- or third-generation cephalosporin (e.g., cefuroxime 1.5 g tid). Local policy may be to add flucloxacillin. Discuss treatment of allergic patients with a microbiologist. Gram stain results may influence the choice of antibiotic.
Patients with MRSA risk (known MRSA, recent inpatient, nursing home resident, leg ulcers or catheters, or other risk factors determined locally)	Vancomycin plus second- or third-generation cephalosporin
Patients with suspected gonococcal or meningococcal infection	Ceftriaxone or similar drug, depending on local policy and drug resistance
Intravenous drug users	Discuss with a microbiologist
ICU patients, those with known colonization of other organs (e.g., cystic fibrosis patients)	Discuss with a microbiologist

Note: The choice of antibiotic will need to be modified in the light of the results of Gram staining and culture. It should also be reviewed locally by microbiology departments. ICU, intensive care unit; IV, intravenously; MRSA, methicillin-resistant Staphylococcus aureus; PO, orally; UTI, urinary tract infection. Reproduced with permission from Mathews CJ, Kingsley G, Field M, et al. Management of septic arthritis: a systematic review. Ann Rheum Dis 2007;66:440-5.

Depending on the initial Gram stain results the treatment may be as follows: If the Gram stain preparation shows gram-positive cocci, the recommended treatment is vancomycin (30 mg/kg daily intravenously [IV] in two divided doses, not to exceed 2 g/day).³⁶ If the Gram-stained specimen shows gram-negative bacilli, the recommended treatment is ceftazidime (1 to 2 g IV every 8 hours) or ceftriaxone (2 g IV once daily) or cefotaxime (2 g IV

every 8 hours). Ceftazidime should be given with an aminoglycoside such as gentamicin (3 to 5 mg/kg/day in two or three divided doses) when *Pseudomonas aeruginosa* is considered to be a likely pathogen (e.g., in patients who inject illicit drugs). In cephalosporin-allergic patients, we suggest treatment with ciprofloxacin (400 mg IV every 12 hours or 500 to 750 mg orally twice daily). If the initial Gram stain results are negative, we treat with vancomycin in immunocompetent patients and with vancomycin plus a third-generation cephalosporin in immunocompromised patients, injection drug users,³⁷ and patients with traumatic bacterial arthritis.

The major part of the destructive process is caused by the inflammatory response of the host directed at live organisms and their products, and thus killing of bacteria does not completely eliminate the destructive process.³⁸ Previous findings have shown a significant benefit of dexamethasone in combination with antibiotics in preventing disability in children with septic arthritis.³⁹ In experimental arthritis, the combination of corticosteroids, antibiotics, and bisphosphonates reduces inflammation and bone and cartilage destruction.

Osteomyelitis

Data from randomized controlled trials that were specifically focused on antimicrobial therapy for vertebral osteomyelitis are lacking, and information on cure rates is derived largely from observational studies.⁹ In a meta-analysis of 22 trials of antibiotic therapy for various types of bone and joint infections, with data on 1-year follow-up, the eradication rate was 79% (95% confidence interval, 66 to 94). With the exception of infections associated with orthopedic devices (for which regimens including rifampin appeared to be superior), there were no significant differences in the outcome related to the specific antibiotic therapy used.⁹

In acute hematogenous osteomyelitis, parenteral antibiotics are initially recommended, and abscesses, if present, need to be drained to prevent subsequent bone necrosis. If treatment has been delayed and necrosis of trabecular bone with sequestrum is present, surgical drainage is recommended. Chronic long-bone osteomyelitis in adults is usually treated with a combination of surgical debridement and specific antimicrobial therapy. Appropriate management of dead bone includes placement of a vascularized bone graft, placement of cancellous bone grafts, or temporary use of antibiotic-impregnated acrylic beads. The optimal duration and route of antibiotic administration is not known, but based on experimental animal studies, a duration of at least 4 to 6 weeks is necessary.⁴⁰ Intravenous administration of a β -lactam at high doses (nafcillin, oxacillin, or cefazolin in infections caused by *S. aureus* and vancomycin in MRSA infections) is initially used during the first 4 to 6 weeks,⁹ followed by oral antibiotics with high bioavailability in osseous tissue such as β -lactam antibiotics, quinolones, and rifampicin. In acute hematogenous osteomyelitis in children, 4 to 6 weeks of treatment is considered the standard therapy. There are no data from controlled trials that suggest the optimal duration of therapy. The recommended duration ranges from 4 to 6 weeks to 3 months.⁹

GONOCOCCAL ARTHRITIS

Gonorrhea is a sexually transmitted disease caused by the bacterium *Neisseria gonorrhoeae*. It usually affects the genital area, but it can also affect the throat, anus, or conjunctiva. It is easily transmitted during vaginal intercourse but it can also be transmitted during anal or oral sex and to a newborn during cervical parturition or from endometrial infection.

Epidemiology

The incidence of gonorrhea has declined significantly in developed countries. Disseminated gonococcal infection (DGI) develops in 0.5% to 3% of patients with untreated mucosal infection depending on the regional prevalence of specific strains. The incidence has now decreased, although it is still high in developing countries. In France and the United Kingdom, *N. gonorrhoeae* arthritis has been reported to be responsible for 1.6% and 0.06% of all cases of septic arthritis, respectively.⁴¹

Microbiology

N. gonorrhoeae is a small, gram-negative, nonmotile, and non-spore-forming bacterium that characteristically grows in pairs (diplococci) and exclusively infects humans. The biologic characteristics of gonococcal strains influence their virulence and the risk of disseminated infection. The ability of gonococci to disseminate has been associated with different factors, such as the presence of pili (see later); the serotypes of protein I (porin) and II (opacity-associated protein); different nutritional requirements for arginine,

Fig. 107.10 Cell membrane structure of *Neisseria gonorrhoeae* and proteins related to infection pathogenesis. LOS, lipo-oligosaccharide; Opa, opacity-associated protein; POR, porin; Rmp, reduction-modifiable protein.

hypoxanthine, uracil, and proline; and the sensitivity to antibiotics. The cell membrane structure of *N. gonorrhoeae* is complex and closely related to the pathogenesis of infection and host defense (Fig. 107.10).

The pilus plays a critical role in forming an initial attachment to host cells. Piliated strains adhere better to epithelium, and the presence of pili is the major determinant of gonococcal morphology in culture and correlates with virulence. Porin, previously designated as protein I, is the most represented outer membrane protein that functions as a pore for the exchange of ions. Porins show stable interstrain antigenic variation and form the basis for gonococcal serotyping. Two main serotypes have been identified: Por.IA strains are usually found in DGI, whereas Por.IB strains cause local infection. These characteristics may be related to the interaction with components of the complement cascade.⁴⁰ Another surface protein that is important for virulence is opacity-associated protein, previously designated as protein II. This protein plays a major role in the formation of intimate associations between the plasma membrane of the host cell and the gonococcus and promotes the invasion of epithelial cells mediated by specific cell-surface receptor interactions.⁴²

Pathogenesis

Host factors also play a role in gonococcal infection and dissemination. Gonococcal infection of the lower female genital tract is typically asymptomatic, partially as a result of the ability of the gonococcus to subvert the alternative pathway of complement. Pregnancy and menses increase the risk of DGI as a consequence of associated changes in the gonococcal phenotype and endometrial exposure of submucosal vessels to the gonococci. In about half of affected women, symptoms of DGI begin within 7 days of the onset of menses. Gonococci have adapted multiple mechanisms by which they are able to evade the lytic action of the complement system, including C4b inactivation and the formation of a nonfunctional membrane attack complex on their cell surface. Inherited or acquired complement deficiency, mainly of the terminal components (C5 to C8), is therefore a risk factor, because serum bacterial activity becomes impaired.

Clinical features

The clinical manifestations of DGI have been classified into two stages: a bacteremic stage and a suppurative stage with infectious arthritis. Some patients, however, may possess features of both (Fig. 107.11).⁴¹

The most common symptoms of DGI are fever, polyarthralgia, tenosynovitis, and skin lesions that have been designated as *acute arthritis and dermatitis syndrome*.⁴³ Tenosynovitis is rare in other forms of septic arthritis and in the presence of skin lesions. Painful joints are also present and

usually include the knees, elbows, and ankles. Tenosynovitis with or without joint involvement occurs in up to 68% of cases. Polyarthralgia occurs in half of patients, and when arthritis is present, it usually involves several joints, with a mildly elevated inflammatory synovial fluid leukocyte count and negative culture results.

Septic arthritis is present in about 50% of cases and is usually monoarticular. Any joint may be affected, but the knees, wrists, ankles, elbows, and small joints of the hands are the most frequently involved.⁴³

Skin lesions are observed in about 75% of patients with DGI in the bacteremic stage (Fig. 107.12).⁴³ They are usually painless, nonpruritic, present in low numbers, and sometimes grouped and appear on the limbs and trunk, sparing the face and scalp. Small macules or papules with an erythematous base are the most common lesions, followed by pustules that sometimes have a hemorrhagic component. A wide variety of skin lesions can be present in DGI, including vesicles, bullae, erythema nodosum, and urticaria. Other unusual manifestations of DGI are gonococcal endocarditis, pericarditis, osteomyelitis, and central nervous system infection with meningitis.

Investigations

In symptomatic men, a rapid diagnosis of gonococcal infection can be obtained by Gram staining of urethral exudates (Fig. 107.13). The sensitivity and specificity of Gram staining are 90% and 95%, respectively, for urethral smears versus 50% to 70% sensitivity and over 90% specificity for endocervical smears.⁴² Only about one fourth of Gram-stained samples of synovial fluid from patients with septic joint arthritis are positive for *N. gonorrhoeae*. Most patients with DGI have no local mucosal symptoms. All potential sites of infection should be screened for gonococcal infection, regardless of the presence of local symptoms. Specimens should be collected with Dacron or rayon swabs, because calcium alginate may be toxic to gonococci and fatty acids inhibit gonococci growth. To minimize the inhibitory effects of unknown substances in the specimen, the swabs should be inoculated directly onto growth medium or placed in a swab transport medium immediately after sampling.⁴² Ideally, the specimens should be inoculated onto culture medium immediately after collection to preserve

the viability of gonococci for isolation. If long-distance shipping is required, the specimens should be inoculated onto media contained in a CO₂-generating system, should be incubated for 18 to 24 hours, and should display visible growth on the plate before shipping.⁴²

Until the late 1980s, laboratory diagnosis of gonorrhea was limited to Gram staining and bacterial isolation. Disadvantages of bacterial culture include the need for invasive collection of specimens that must be transported under appropriate conditions to maintain organism viability. The current recommendation of the Centers for Disease Control and Prevention is that only bacterial culture should be used to test for pharyngeal or rectal gonorrhea. Molecular detection methods allow for more rapid and specific diagnosis of pathogens that are fastidious or cannot be cultured. These methods permit the use of specimens that are unsuitable for culture, such as urine and vaginal swab samples, which can be obtained from patients without discomfort. The lower sensitivity of bacterial culture of specimens from extragenital sites may be attributed to the heavy colonization of these sites by a broad range of other organisms, including other *Neisseria* species, which may interfere with *N. gonorrhoeae* isolation.⁴⁴

In the early 1990s, nucleic acid amplification tests (NAATs) first became available for routine use. There are several advantages of *N. gonorrhoeae* NAATs. First, they offer greater sensitivity than bacterial culture. When compared with *N. gonorrhoeae* NAATs, gonococcal culture ranges in sensitivity from 85% to 95% for acute infections and may fall as low as 50% for females with chronic infection. The increased sensitivity of NAATs makes them particularly suitable for screening, which allows accurate diagnosis of both symptomatic and asymptomatic gonococcal infections, a critical factor in controlling the disease. Second, specimens collected for NAAT assays do not need to contain viable organisms to allow detection, so that transport conditions are less stringent than those for specimens collected for bacterial culture. Finally, NAATs can be used effectively on noninvasively collected specimens, such as urine and self-collected samples. A notable limitation of *N. gonorrhoeae* NAATs is the inability to provide data on antibiotic resistance, which is an emerging health concern given the increased reports of the antibiotic resistance of *N. gonorrhoeae*.⁴⁴

Management

DGIs require higher dosages and longer durations of therapy than uncomplicated infections. Penicillin resistance results either from the acquisition of plasmids that encode β -lactamase or from chromosomal mutations.⁴⁵ Quinolone-containing regimens are no longer recommended, because resistance to these drugs has been well documented. Hospitalization is indicated

Fig. 107.11 Spectrum of the clinical manifestations of DGI. The bacteremic form is on the left and the suppurative form is on the right, with overlapping forms in the middle.

Fig. 107.12 Skin lesions in disseminated gonococcal infection. (a) Macules, papules, and pustules over an ankle. (b) Hemorrhagic papules localized in the trunk. (c) Hemorrhagic vessel over a distal interphalangeal joint. (c, Courtesy Dr. Peter Schlessinger.)

if the diagnosis is uncertain, if there is a purulent arthritis that requires aspiration, or if the patient cannot be relied on to comply with the treatment regimen. A cephalosporin-based intravenous regimen is recommended for the initial treatment of DGI. This is particularly important when gonorrhea is detected at mucosal sites by nonculture tests. Daily ceftriaxone (1 g IV) is the first choice for antimicrobial therapy, although other third-generation cephalosporins, such as cefotaxime (1 g IV every 8 hours) or ceftizoxime (1 g IV every 8 hours), can also be prescribed. Patients who are allergic to β -lactam drugs can be treated with spectinomycin (2 g intramuscularly every 12 hours). Treatment should be continued for 24 to 48 hours after clinical improvement, at which time therapy may be changed to one of the following regimens (to be prescribed for at least 1 week of antimicrobial therapy): cefixime 400 mg orally twice daily, cefixime suspension 400 mg (200 mg/5 mL) twice daily, or cefpodoxime 400 mg orally twice daily.⁴⁶ Infected joints should be aspirated until the infection resolves, and open drainage is rarely necessary.

Because of the high rate of other sexually transmitted diseases, a diagnostic test for *Chlamydia trachomatis* should also be performed.

SYPHILITIC ARTHRITIS

Syphilis is a sexually transmitted chronic systemic infection caused by *Treponema pallidum* and is characterized by episodes of active disease followed by asymptomatic periods or latency. This is especially important in light of the increasing rates of syphilis, as well as the increasing recognition of concurrent syphilis and HIV infection. A systematic review of the literature found that between 2000 and 2004, the number of reported cases of primary and secondary syphilis increased by 33%.⁴⁷

Clinical features

Musculoskeletal symptoms may appear in the congenital, secondary, or tertiary phases of syphilis but are most common in the secondary stage.⁴⁸ The

most common manifestations of early congenital syphilis are bone changes, which include osteochondritis, osteitis, and periostitis. The symmetric destruction of the medial aspect of proximal tibial metaphyses (Wimberger sign) is usually pathognomonic for congenital syphilis. In 23% of patients, there is epiphyseal separation or fracture of the long bones, which prevents limb movement and results in pseudoparalysis.⁴⁹ Late congenital syphilis (more than 2 years) is usually subclinical. Joint complaints are characterized by painless bilateral effusion of the knees or elbows without local or systemic symptoms, often described as *Clutton joints*.⁴⁸ Neuroarthropathy due to tabes or Charcot joint, which affects the hips or knees, is the most common musculoskeletal manifestation of tertiary syphilis and is due to the loss of deep sensation and chronic trauma rather than direct infection of the joint.

Investigations

Laboratory diagnosis of syphilis is based on visualization of the *Treponema* species and/or demonstration of specific antibodies. Historically, screening for syphilis has involved the use of nontreponemal tests, such as the serum rapid plasma reagin or Venereal Disease Research Laboratory test. When results are positive, the disease is then confirmed using a more specific treponemal test, such as the *T. pallidum* hemagglutination test or the fluorescent treponemal antibody absorption test. In recent years, new diagnostic tests for syphilis such as the immunochromatography strip test, Western blot analysis, and use of nucleic acid amplification or molecular strain typing have been developed.

Management

Penicillin remains the drug of choice for the treatment of syphilis, but the doses and regimens vary with disease stage. Several studies have shown that azithromycin may have a similar clinical efficacy. Macrolide resistance has been documented among strains of *T. pallidum*, however, and treatment failures have been reported. Ceftriaxone is also effective for the treatment of syphilis when used in multiple-dose regimens.⁴⁹

Infectious arthritis II: mycobacterial, brucellar, fungal, and parasitic arthritis

■ JAVIER MARQUEZ ■ LUIS R. ESPINOZA

- Human immunodeficiency virus infection and treatment with biologic agents are associated with an increased frequency of infectious musculoskeletal complications.
- Mycobacterial infections, especially infection with *Mycobacterium tuberculosis*, remain a concern.
- A good prognosis requires prompt and accurate diagnosis, which necessitates a high index of suspicion, particularly for rare infections.
- Novel molecular techniques are improving diagnosis, but careful clinical assessment is still mandatory.
- Effective antimicrobial therapies are available for most disorders, but resistance to these agents is an increasing concern.

INTRODUCTION

Musculoskeletal infectious disorders caused by mycobacterial, brucellar, fungal, and parasitic microorganisms are uncommon and difficult to diagnose. A resurgence of musculoskeletal infectious disorders is being seen triggered by a variety of factors, including the pandemic of human immunodeficiency virus (HIV) infection and increased use of immunosuppressive medications, including tumor necrosis factor- α (TNF- α) inhibitors.¹

TUBERCULOUS ARTHRITIS

Epidemiology

Tuberculosis remains a leading cause of morbidity and mortality. Cases of multidrug-resistant tuberculosis (resistance to isoniazid and rifampicin) and extensively drug-resistant tuberculosis are increasing.

In the United States, 10,521 cases of tuberculosis (3.4 cases per 100,000 inhabitants) were reported during 2011; this represents a 6.4% decrease compared with 2010. Despite a nationwide decline, foreign-born persons and racial and ethnic minorities continue to bear a disproportionate burden of tuberculosis disease. In 2011 the rate of tuberculosis in foreign-born individuals in the United States was 12 times higher than in the native population. The Asian populations had the largest number of cases.²

Pathophysiology

The genus *Mycobacterium* comprises several species. However, only two species of *Mycobacterium tuberculosis* complex (*M. tuberculosis* and *M. bovis*) are associated with significant human disease. Worldwide, *M. tuberculosis* is the most common cause of tuberculosis.

M. tuberculosis infection occurs through inhalation of aerosolized bacteria, ingestion of bacteria, or direct inoculation from infected individuals. The occurrence of *de-novo* infection depends on the number of organisms that survive phagocytosis and their ability to escape host defenses, such as alveolar macrophages (pneumocytes) and delayed hypersensitivity responses. Mycobacteria multiply intracellularly using Toll-like receptor 2 and receptors that bind complement, mannose, cholesterol-related receptors, and CD14, which leads to a burst of the pneumocytes. Released organisms are then phagocytized by other macrophages, and a chain reaction

ensues with cytokine production triggering an inflammatory response and eventually leading to hematogenous spread to distant organs. Microorganisms invading regional lymph nodes initiate the development of protective immunity that is mediated mainly by CD4+ lymphocytes with help from CD8+ cytotoxic lymphocytes and also B cells. Cytokines, such as interleukin-1 (IL-1), IL-2, IL-6, IL-12, interferon- γ (IFN- γ), and TNF- α , play a key role in protection against tuberculosis and also in formation and maintenance of granulomas (Ghon lesions). Tuberculosis related to anti-TNF inhibitors may be due to inhibition of a TNF-dependent chemokine gradient disrupting the cellular migration necessary to maintain the integrity of granulomas.³

Musculoskeletal manifestations

Bone and joint infections account for 1% to 3% of all forms of tuberculosis. Although 50% of patients have pulmonary tuberculosis, extrapulmonary disease accounts for up to 35% of cases. Musculoskeletal involvement (9% of cases) is considered the fifth most common extrapulmonary form, after lymphatic (27%), pleural (21%), genitourinary (16%), and miliary (10%) forms.

Skeletal tuberculosis has a tendency to involve weight-bearing joints, and several clinical patterns are described, including spondylitis, peripheral arthritis, reactive arthritis or Poncet disease, osteomyelitis, and soft tissue abscesses (Box 108.1).

Spondylitis (Pott disease)

Tuberculosis spondylitis may affect the vertebrae, intervertebral disks, paraspinal soft tissues, and epidural space. Unlike pyogenic osteomyelitis, tuberculosis spondylitis is characterized by a subacute course and lower disease activity.

Spondylitis comprises the most common form of osteoarticular tuberculosis and results from secondary hematogenous spread from a primary focus mainly localized in lungs, lymph nodes, and other tissues. The vertebral column is affected in 50% of cases of skeletal tuberculosis, and the thoracic and lumbar regions are the most frequent sites. Infection in the early stages is localized in the anterior subchondral bone of a vertebra adjacent to the intervertebral disk, resulting in narrowing of the disk space. In later stages, progression is evident 2 to 5 months after onset and first involves cancellous and, subsequently, cortical bone. Magnetic resonance imaging (MRI) findings have not significantly reduced the diagnostic delay.⁴

The characteristic form of presentation is back pain, localized in the thoracic and/or lumbar regions and accompanied by generalized malaise, low-grade fever, weight loss, and night sweats. Onset of symptoms has an average duration of approximately 1 year. It is usually insidious and varies from weeks to years. Vertebral collapse can occur, producing the classic radiologic picture of anterior wedging of two adjacent vertebral bodies with destruction of the intervening disk and the physical finding of a tender spinal prominence or gibbous deformity.

Radiologic findings suggestive of a tuberculosis cause include slow progression of lesions with preservation of disk space, involvement of several contiguous segments, the presence of large intraosseous and paraspinal abscesses containing calcifications, and body collapse with kyphotic deformity.⁵

Diagnosis is often delayed until signs of advanced disease occur, such as paraparesis and paraplegia, reported in 4% to 30% of cases. The most common findings are sensory deficit symptoms secondary to spinal cord or

- Tenosynovitis and bursitis
- Soft tissue abscess
- Reactive arthritis (Poncet disease)

nerve root involvement, which may appear before spinal deformity. Kyphosis is a late finding, and its combination with scoliosis produces the gibbous deformity.

Peripheral arthritis

Peripheral skeletal involvement is usually monoarticular, chronic, and insidious, but multiple joints may be involved. Any large joint can be affected, including hips (15%), knees (15%), and ribs (5%).⁶ In endemic areas, children and young adults are affected most often.

In a study in Taiwan of 51 adult patients with tuberculosis arthritis the mean duration of symptoms and signs before diagnosis was 25 months (range, 0 to 180 months).⁷ Joint pain (96%) and swelling (90%) were common. Forty-five patients (88%) had monoarthritis; arthritis of the knee (27%) was the most common. Twenty-six patients (51%) had radiologic evidence of pulmonary tuberculosis, and 43 patients (84%) had synovial fluid and/or tissue cultures positive for *M. tuberculosis*. One fourth of patients reported a history of previous trauma.

Osteomyelitis

Osteomyelitis occurs in children and adults and comprises 2% to 3% of osteoarticular tuberculosis. Any bone may be involved, but the femur and tibia are the most common, followed by short bones such as metacarpals, metatarsals, and phalanges.

Bony involvement is secondary to hematogenous dissemination of mycobacteria in the diaphysis with fusiform, painful swelling that clinically resembles inflammatory arthropathy, which causes a diagnostic dilemma. Tuberculous osteomyelitis outside the vertebral body presents as a cold abscess, with swelling and only modest erythema or pain.

Reactive arthritis (Poncet disease)

Reactive arthritis or Poncet disease is characterized by polyarthritis associated with extrapulmonary tuberculosis with no evidence of direct joint involvement. It affects young people and is slightly more common in women. Findings include fever, malaise, and polyarthritis of large joints such as knees, ankles, and, at times, wrists. The tuberculin test result frequently is positive, and the extrapulmonary site of tuberculosis is usually lymph nodes. Reactive arthritis responds well to nonsteroidal antiinflammatory drugs (NSAIDs).

Soft tissue abscess and panniculitis

Soft tissue abscesses are rare but may be associated with vertebral involvement (paravertebral abscess) and osteomyelitis. In contrast, panniculitis presenting as erythema nodosum is often seen with or without polyarthritis. Erythema induratum—a variety of panniculitis associated with vasculitis and at times with arthritis around the ankles, also known as *Bazin disease*—can be seen.

Cold abscesses (which develop slowly and with minimal inflammatory reaction and become painful only in the presence of pressure on the surrounding area) can appear after treatment has been initiated and in some cases are visible by only computed tomography (CT) or MRI in areas such as the spine, hips, lymph nodes, or genital region.

Diagnosis

The gold standard for diagnosis remains the identification of *M. tuberculosis* by microbiologic or histologic techniques. An elevated erythrocyte sedimentation rate (ESR) and C-reactive protein level may be present, but these indicators lack specificity. Culture is an important and sensitive diagnostic tool (80% positivity). More sophisticated techniques using polymerase

Fig. 108.1 Pott disease. Vertebral destruction with paraspinal soft tissue enlargement can be noted. (Courtesy Dr. Sergio Alvarez, Radiology Department, Hospital Pablo Tobon Uribe, Medellin, Colombia.)

chain reaction (PCR) or nucleic acid amplification tests that detect *M. tuberculosis* genetic material and amplify target sequences are even faster and may replace conventional procedures, and can be used in patients with negative smear results.

Skin testing with purified protein derivative and whole-blood IFN- γ -releasing assays are used to screen individuals and are discussed in detail in Chapter 65. Adenosine deaminase levels in serum or pleural fluid may provide a clue to a diagnosis of tuberculosis. Its levels increase in patients with tuberculosis independent of therapy with disease-modifying antirheumatic drugs or TNF- α inhibitors. Synovial fluid is nonhemorrhagic, turbid, and xanthochromic. White blood cell counts are moderately elevated to between 10,000 and 20,000 cells/mm³ with a predominance of polymorphonuclear leukocytes. Synovial tissue shows caseating granulomas in up to 80% of specimens.

Other diagnostic tests include the microscopic observation direct susceptibility assay, which allows for rapid detection of *M. tuberculosis* growth. Line probe assays for rapid drug susceptibility testing and urine tests for the diagnosis of tuberculosis are promising tools.⁸

Imaging

Radiologic techniques are useful to confirm the diagnosis. In addition, ultrasonography, CT, and MRI can be used to guide needle aspiration in sites that are difficult to access.

Spondylitis

Early abnormalities include resorption of the dense margins of the endplates and demineralization, narrowing or obliteration of the disk space, and soft tissue swelling (paravertebral abscess [Fig. 108.1]). Late-stage findings include lytic progressive destruction of the anterior vertebral body, vertebral collapse, and kyphosis.

CT reveals small abnormalities and paravertebral abscesses (which may occur in 50% of patients). MRI is the main diagnostic modality, provides higher soft tissue definition than CT, and is more specific for delineating swelling⁹ (see Fig. 108.1).

Peripheral arthritis

Soft tissue and joint swelling with effusion are seen in early stages. Later on, peripheral osseous erosions, articular destruction with narrowing of joint space, and juxtaarticular osteoporosis (Phemister triad) are evident. Bone involvement may be difficult to distinguish from pyogenic infection. Margin erosions are more common and the joint space is preserved for a longer period because tuberculosis progresses more slowly than pyogenic infection. CT, MRI, and scintigraphy are recommended to establish a diagnosis.

Osteomyelitis

Findings include cavity formation in 50% of cases, lytic lesions with blurred margins, and minimal or no reactive bone sclerosis. Bone sequestration

Fig. 108.2 Tuberculous osteomyelitis. There is soft tissue enlargement and the presence of air at the thigh with femur involvement. (Courtesy Dr. Sergio Alvarez, Radiology Department, Hospital Pablo Tobon Uribe, Medellin, Colombia.)

Fig. 108.3 Tuberculous osteomyelitis. A lytic bone lesion and blurred margin with cavitation of the femur can be seen. (Courtesy Dr. Sergio Alvarez, Radiology Department, Hospital Pablo Tobon Uribe, Medellin, Colombia.)

is rarely seen. However, subsequently, new subperiosteal bone develops, which produces the typical enlargement of the shaft¹⁰ (Figs. 108.2 through Fig. 108.4).

Treatment

Most recommended treatment regimens should be administered for at least 9 to 12 months. First-line drugs include 8 weeks of oral daily treatment with isoniazid 5 mg/kg (up to 300 mg), plus rifampin 10 mg/kg or 600 mg, plus pyrazinamide according to body weight 40 to 45 kg: 1000 mg, 56 to 75 kg: 1500 mg, 76 to 90 kg: 2000 mg, and ethambutol 15 mg/kg, or streptomycin 15 mg/kg or 1 g intramuscularly. Then, 28 to 36 weeks of treatment with isoniazid plus rifampin for 5 days/wk to complete 9 to 12 months of treatment. Pyridoxine 25 to 50 mg daily may be added to daily regimens that include isoniazid.

Other therapeutic modalities include the treatment of latent *M. tuberculosis* infection with isoniazid 5 mg/kg or 300 mg orally daily; or 15 mg/kg (up to 900 mg) twice weekly under supervision. The optimal duration of the therapy is 9 months, although in some situations a shorter course of 6 months may be considered for cost effectiveness. Alternatively, rifampin 600 mg/day given orally for 4 months is effective in HIV-infected and non-HIV-infected patients.

Treatment of multidrug-resistant tuberculosis includes regimens with combinations such as rifampin, ethambutol, pyrazinamide, quinolones, macrolides, and/or amikacin or streptomycin.

There are five principles in the treatment of multidrug-resistant tuberculosis: (1) Culture the bacilli and use drug sensitivity to guide therapy. (2) Never add a single drug to a failing regimen. (3) Use of four-drug regimens not administered previously is mandatory. (4) An injectable aminoglycoside should be added for at least 2 months. (5) A minimum treatment duration of 24 months is highly recommended.^{11,12}

In general, the clinical response to therapy is adequate, but patients should be monitored carefully for treatment-related toxicity. Other

Fig. 108.4 Computed tomographic scan with digital reconstruction showing involvement of the seventh rib by tuberculosis. (Courtesy Dr. Sergio Alvarez, Radiology Department, Hospital Pablo Tobon Uribe, Medellin, Colombia.)

therapeutic modalities, such as surgery, are indicated when large abscesses are present and in selected cases of vertebral tuberculosis (e.g., acute neurologic involvement or deterioration, paraparesis, or paraplegia) and/or spinal instability or deformity of more than 5 degrees. It is recommended that 1 to 4 weeks of drug therapy be administered to stabilize the general condition of patients before any surgical procedure is performed.

Prevention

Vaccination is a valuable tool and is widely employed in Latin America, Africa, Asia, and some European countries to prevent tuberculosis infection. Bacille Calmette-Guérin vaccine seems to be effective in some populations but not in others. Administration of repeated doses can increase its effectiveness.

Tuberculosis related to treatment with anti-tumor necrosis factor- α and biologic agents

Tuberculosis is a complication seen most commonly with anti-TNF therapy, but this infection has also occurred with other biologics (see Chapter 67).

LEPROSY AND OTHER ATYPICAL MYCOBACTERIAL INFECTIONS

Epidemiology

Leprosy has a low incidence and prevalence in developed countries. In 1998, 102 cases of leprosy were registered in the National Hansen's Disease Program in the United States. In 2010, according to the World Health Organization (WHO), the global figure reported for leprosy was 228,474 new cases, with the lowest rates seen in the Western Pacific region and the highest rates seen in Africa and Southeast Asia. India, with 126,800 patients, led the list of countries with the highest rates of incidence, followed by Brazil with 34,894 patients.¹³

Atypical mycobacterial infections may occur in healthy individuals with certain occupational exposures but are more common in immunocompromised individuals, including patients receiving corticosteroid therapy.

Microbiology

Despite significant efforts, *Mycobacterium leprae* cannot be cultured *in vitro*. *M. leprae* is a gram-positive and acid-fast rod-shaped organism. *M. leprae* and other atypical mycobacteria affect the musculoskeletal system. Infection usually derives from either hematogenous spread or percutaneous inoculation. *Mycobacterium avium-intracellulare*, *Mycobacterium chelonae*, *Mycobacterium fortuitum*, *Mycobacterium haemophilum*, *Mycobacterium marinum* (in fish handlers), and *Mycobacterium kansasii* most commonly cause skeletal infections, usually through penetrating injuries.

Clinical features

The clinical spectrum is highly variable and depends on the causative agent. Leprosy is a chronic infection, and its features range from a nonsensitive or hypopigmented skin spot (tuberculous) to severe neuropathic and osteo-articular damage (lepromatous). Common to both types of lepra reaction are pain and swelling at sites of infection. Well-recognized musculoskeletal features of leprosy include neuropathic or Charcot joints, septic arthritis, acute polyarthritis of lepra reactions, and chronic/subacute rheumatoid-like polyarthritis (Box 108.2).

The Lucio phenomenon is an uncommon but severe form of reaction in multibacillary leprosy. It can manifest as bluish or violaceous and hemorrhagic plaques followed by large recurrent ulcerations in the lower extremities and may be fatal.¹⁴

Leprosy has a wide range of clinical manifestations, including infection of the nasal mucosa and cartilage, which may lead to saddle-nose deformity. *M. leprae* invades Schwann cells and the glial cells of the peripheral nervous system, and generally, thermal sensation is lost before the ability to sense pain and pressure. Leprosy tends to flare up either spontaneously or after the onset of treatment. In one study in 2004 involving 1257 leprosy patients at an outpatient clinic in the state of Amazonas, Brazil, 115 patients (9%) had articular involvement, 24 had arthralgias, and 55 had leprosy-related arthritis.¹⁵ Prevalence of arthritis was similar in both genders, and all patients had lepromatous or borderline disease type. Most patients had polyarticular and symmetric arthritis, and mean duration of articular

BOX 108.2 CLINICAL FEATURES OF LEPROSY

- Neuropathic or Charcot joints
- Septic arthritis
- Acute polyarthritis
- Rheumatoid arthritis-like involvement
- Cutaneous ulcerations (Lucio phenomenon)

Fig. 108.5 Leprosy involving the right foot with marked soft tissue edema, bone resorption, and diffuse phalangeal lytic lesions. (Courtesy Dr. Vanessa Garcia, Radiology Department, University of Antioquia, Medellín, Colombia.)

symptoms was 1 year (range, 5 days to 14 years). In all, 91% had erythema nodosum leprosum or reversal reactions. Most arthritis cases were considered reactive episodes, and the arthritis had a chronic course and was not responsive to conventional therapy.

The clinical picture of atypical *Mycobacterium* infection consists of constitutional symptoms such as malaise, weight loss, low-grade fever, and local pain. Musculoskeletal complications include tenosynovitis, soft tissue abscess, and osteomyelitis.

Diagnosis

Findings are nonspecific: an elevated ESR, anemia, and positivity for rheumatoid factor are seen in up to 30% of patients. Synovial fluid is usually a transudate. All infections, including infection with *M. leprae*, require histopathologic or bacteriologic demonstration of the organism in tissue samples, such as nasal swab specimens (leprosy) and/or biopsy specimens from soft tissue lesions, by conventional or newer techniques such as PCR assay. Radiographic features include multiple involved areas of the metaphysis and diaphysis of long bones, lytic areas with erosions in small joints, sclerosis, and osteoporosis (Figs. 108.5 and 108.6). Nerve involvement (three or more) and delay in treatment are significant markers of disability, with odds of 3.73 and 2.27 respectively.¹⁶

Treatment

Treatment of leprosy consists of specialized medications and physical rehabilitation to avoid joint contractures. The WHO recommends the use of multidrug therapy due to an increasing resistance to dapsone. Dapsone 100 mg orally daily and rifampin 600 mg once a month for 12 months are recommended for treatment of the paucibacillary form. Multibacillary infection should be treated with dapsone 100 mg daily, rifampin 600 mg monthly, plus clofazimine 50 mg daily for 2 years.

Combination therapy is needed for infection with *M. avium-intracellulare*, *M. chelonae*, *M. fortuitum*, and other atypical mycobacteria and includes macrolides (clarithromycin or azithromycin), ethambutol, and a third drug to be chosen from among rifampin (or rifabutin), ciprofloxacin, amikacin, cefoxitin, clofazimine, and tetracycline. Duration of treatment remains to be established and varies from 12 to 18 months.

BRUCELLOSIS

Epidemiology

Brucellosis is a chronic granulomatous infection caused by intracellular bacteria that has public health implications. Transmission to humans occurs by consumption of contaminated food, mainly non pasteurized dairy products (cheese), associated with poor animal husbandry methods and hygiene standards. Populations in several countries in Europe are affected, including Spain, Greece, and Turkey. The Mediterranean region and the Arabian peninsula are endemic areas. India and Africa are also affected areas. In the Western Hemisphere, Mexico and Central and South America (particularly Brazil, Colombia, and Peru) are highly endemic areas. In the United States, brucellosis is considered a rare disease; approximately 100 cases are reported yearly. The incidence in endemic regions varies from 1 to 200 per 100,000 inhabitants, and the prevalence of the disease varies widely in these regions.

Microbiology

Brucellosis is caused by organisms of the genus *Brucella*, which is composed of at least 10 species.¹⁷ The *Brucella* organism is a small gram-negative coccobacillus.

Clinical features

Brucellosis is a systemic acute or insidious illness that usually follows a chronic course and is rarely fatal. Acute brucellosis presents as a flulike illness, including undulating fever, sweats, headaches, back pains, and weakness, whereas chronic brucellosis manifests as recurrent fevers, joint pain, fatigue, and complications of sacroiliitis, peripheral arthritis, spondylitis, osteomyelitis, and bursitis (Fig. 108.7, Box 108.3).

In a study of 195 patients no gender predisposition was seen, and individuals 15 to 45 years of age were most commonly affected.¹⁸ Sacroiliitis (55% of cases) was the most common manifestation, followed by peripheral joint involvement (54%) and spondylitic involvement (31%). Monoarthritis was the predominant pattern of peripheral involvement, with hips (58% of cases) and knees (22%) commonly affected.

Plain radiographs confirm axial involvement, although imaging studies such as MRI are helpful for the detection of early findings. Genetic

Fig. 108.7 Magnetic resonance imaging (MRI) scan of a 35-year-old Hispanic male with brucellar spondylitis. The patient had persistent fever, weight loss, and spondylodiskitis with intervertebral disk involvement and abnormal uptake of contrast agent in T7 and T8, and L2 and L3 on MRI. (Courtesy Dr. Luis F. Pinto, Rheumatologist, Hospital Pablo Tobón, Medellín, Colombia.)

predisposition may play a role, and HLA-B39 was found to be increased in patients with brucellosis who had musculoskeletal involvement.

In 231 Turkish patients the source of infection was unpasteurized milk and milk products (cheese). Thirty-seven percent of patients were classified as having an acute presentation (less than 3 months), 19% as having a subacute presentation (3 to 12 months), and 44% as having a chronic presentation (longer than 12 months).¹⁹ Fatigue, fever, anorexia, nausea, and diarrhea were significantly higher in the acute stage; weight loss and palpitations were significantly more frequent in the subacute stage; and osteoarticular manifestations were significantly more frequent in the chronic stage. Sacroiliitis was the most common complication, followed by spondylodiskitis, bursitis, and osteomyelitis. The lumbar spine was the most frequent site of spondylodiskitis (56%), and the cervical spine was least affected (4%).¹⁹

Other manifestations include intermittent or irregular fever of variable duration, malaise, malodorous perspiration, depression, weight loss, uveitis, hepatosplenomegaly, and lymphadenopathy. Relapses (first year) are relatively common (approximately 10%) and for the most part are caused by inadequate treatment. Childhood brucellosis tends to exhibit a more benign course and responds better to treatment.

BOX 108.3 RHEUMATIC MANIFESTATIONS OF BRUCELLOSIS

- Sacroiliitis, 40%-55%
- Peripheral arthritis, 30%-40%
- Spondylitis, 20%-30%
- Osteomyelitis, 5%-10%
- Bursitis, 2%-5%
- Reactive arthritis, ?

BOX 108.4 CHARACTERISTICS OF FUNGAL MUSCULOSKELETAL INFECTIONS

- Low incidence and occupation-related disease
- Occurrence in tropical or subtropical areas
- Occurrence in immunocompromised hosts
- Subacute or chronic course
- Pulmonary and/or cutaneous involvement important as extraarticular manifestations
- Definitive diagnosis requiring demonstration of fungi

Diagnosis

The diagnosis requires a high index of suspicion and isolation of the bacterium from blood or tissue samples. Elevations in ESR (49%) and C-reactive protein level (20% to 25%) may be seen but are nonspecific findings. Anemia (30%) and elevated transaminase levels (10%) are also found. Synovial fluid is inflammatory but sterile. Specific antibody titers may be detectable at presentation or will rise over 2 to 3 weeks. Titers above 1:160 in any of the agglutination tests in conjunction with typical clinical findings are considered diagnostic. High titers persist for up to 18 months, which makes it difficult to use these tests for follow-up. Blood culture yields a positive result in 50% to 80% of cases, even in afebrile patients.

Treatment

The intracellular character of *Brucella* infection associated with an acidic environment requires treatment with antibiotics that can penetrate macrophages and reach adequate concentration—preferably used in combination. The WHO recommends two regimens, both of which use doxycycline orally (100 mg every 12 hours) plus rifampin 900 mg/day for a 45-day period. Or the same dose of doxycycline for 45 days in combination with streptomycin IM (1 g daily) for 2 weeks. In general, the response to treatment and outcome are excellent.

Alternative drug combinations may be used, such as other aminoglycosides (e.g., gentamicin and netilmicin), trimethoprim-sulfamethoxazole, and quinolones (especially in patients with spondylitis and for a minimum of 3 to 6 months). Rifampin is the drug of choice during pregnancy. Brucellosis in children is treated with combinations that include rifampin, trimethoprim, and aminoglycosides.

Prevention

Vaccination of uninfected animals and culling of infected animals have successfully eradicated brucellosis from most of the United States; however, there are countries without resources to implement effective eradication programs.

FUNGAL MUSCULOSKELETAL INFECTIONS

Based on the study of some genetic and immunologic disorders known to predispose to invasive fungal infections, defects in phagocyte effector function, abnormalities in IL-12, IFN- γ signaling, and mutations in GATA2 have been identified as playing important roles. These advances translate into new powerful and specific antifungals.²⁰

Patients at risk include immunocompromised hosts with systemic underlying diseases such as HIV infection, systemic lupus erythematosus, rheumatoid arthritis (RA), and malignancies, as well as patients receiving immunosuppressive therapy, including corticosteroids and biologic agents. In addition, residence in endemic areas such as tropical and subtropical regions, as well as some occupations, may also be associated with a higher incidence.

Definitive diagnosis requires demonstration of the fungi. Clinical findings, serologic test results (Box 108.4, Table 108.1), and tissue biopsy samples play an important role. The gold standard in diagnosis is culture.

Treatment includes a combination of antimycotic drugs, with or without surgery.²¹ Amphotericin B remains the cornerstone of treatment.

Histoplasmosis

Histoplasmosis is a worldwide mycosis, although it is highly endemic in Ohio and Mississippi in the United States and Central and West African countries. The incidence of endemic mycoses (number of cases per 100,000 person-years) among a cohort of Medicare beneficiaries from 1999 to 2008

TABLE 108.1

Serologic fungal tests

Fungi	Antibodies				Antigens
	CF	ID	ELISA	Other	LA

was as follows: histoplasmosis, 357; coccidioidomycosis, 345; and blastomycosis, 74; the Midwest was the most common location.²²

Histoplasma capsulatum is a dimorphic fungus that is found in soil. Infection occurs after the spores are inhaled and phagocytized by *in situ* pneumocytes. Direct inoculation in the skin has been reported in rare cases. Although histoplasmosis remains a rural disease, occupational hazards are encountered by individuals exposed to the droppings of urban-living birds and by cave explorers in contact with bat and bird guano after disturbance of contaminated soil.

Macrophages and dendritic cells are the principal effectors in host resistance, whereas T cells contribute to host defense with the production of cytokines to activate mononuclear phagocytes. TNF- α , IFN- γ , and IL-12 play a role in controlling primary infection. Histoplasmosis may be an important complication of treatment with TNF- α inhibitors. The clinical presentation of histoplasmosis (pulmonary, extrapulmonary, or disseminated) may mimic that of some rheumatic diseases, which may delay recognition and treatment.

H. capsulatum infection is frequently asymptomatic and self-limited in the healthy host. Migratory polyarthralgias/arthritis involving large joints (knees, ankles, and wrists), tenosynovitis, myalgias, and erythema nodosum are the most common musculoskeletal manifestations (Fig. 108.8). Patients may also exhibit fever, headaches, and cough. Disseminated histoplasmosis can occur in as many as 1 per 2000 cases of infection. Risk factors include immunosuppression, age older than 54 years, renal transplantation, and use of anti-TNF- α inhibitors. Chest radiographs are mandatory to rule out lung involvement. Serologic or urinary tests are also useful techniques. Tissue biopsies and/or culture are mandatory.

Treatment

Most cases of acute histoplasmosis do not require specific treatment. Symptomatic management with NSAIDs may suffice. Severe, persistent, or progressive disease in an immunocompromised host requires specific antifungal drugs. New antifungal agents, including several azoles such as voriconazole, caspofungin, and lipid-based preparations of amphotericin B, are available.

Mild to moderate disease in progressive disseminated histoplasmosis should be treated with itraconazole 200 mg orally 3 times a day for 3 days, then 200 mg twice daily for at least 12 months. However, for severe and/or life-threatening infections such as meningitis, amphotericin B is the choice. Severely immunocompromised hosts can be treated with liposomal amphotericin B 3 mg/kg/day intravenously for 1 to 2 weeks followed by suppressive therapy with itraconazole. Surgical débridement is often required.²³

Fig. 108.8 Forty-one-year-old Hispanic female who developed dermatomyositis while taking steroids, complicated by biopsy-confirmed histoplasmosis-induced panniculitis. She was treated successfully with amphotericin B.

Blastomycosis

Blastomycosis is caused by the dimorphic fungus *Blastomyces dermatitidis* and has a widespread distribution. It is endemic to central and southeastern regions of the United States but is also seen in Mexico, the Middle East, Africa, and India. The fungus is acquired by inhalation, and dissemination occurs from lungs to skin (80%) and to bones (60%), where osteolytic lesions exhibit a mild periosteal reaction and no sequestra formation, resembling a neoplasm.

Onset of illness is usually abrupt (but may be insidious). Lungs are the major targets, and complaints include cough, headaches, chest pain, weight loss, fever, abdominal pain, night sweats, chills, and anorexia. Cutaneous involvement is the most common extrapulmonary feature, followed by bone and joint manifestations.

In a Canadian study of 45 patients with blastomycosis there were 41 cases of osteomyelitis and 12 cases of septic arthritis. The majority were men (35 patients [78%]) and non-Aboriginal (32 patients [71%]). Cutaneous disease was present in 33 patients (73%) and lung involvement in 29 (64%). The most common sites of osseous involvement were the lower limbs and axial skeleton. Features included bone pain in 42 patients (78%), swelling in 32 patients (59%), and soft tissue abscesses in 21 patients (39%). Joint infection occurred in 12 patients and manifested as a monoarthritis presenting with effusion in 9 patients (75%), pain in 8 patients (67%), and decreased range of motion in 5 patients (42%).²⁴

Delay in diagnosis is common, and the differential diagnoses include endemic fungal infections and bone tumors. Histopathologic evidence of broad-based budding yeast and serologic evidence of *B. dermatitidis* infection confirms the diagnosis.

Less than 5% of cases of disseminated infection involve the central nervous system, the meninges, or the brain itself.

Serologic tests are not helpful, but enzyme-linked immunosorbent assay (ELISA) seems to have greater sensitivity than other tests; however, immunodiffusion and complement fixation tests have better specificity. Synovial fluid examination or tissue biopsy should be performed whenever possible. The fungus grows slowly in culture. Radiographs may show an eccentric lucency in the distal end of large bones and osteopenia in the involved location.

Treatment

Blastomycosis is managed with itraconazole oral solution 200 mg administered 3 times a day for 3 days, then 200 mg once or twice a day for 12 months. Surgical débridement or drainage is helpful to accelerate healing. In refractory or life-threatening disease, liposomal amphotericin B (5 mg/kg/day) or amphotericin B 0.7 to 1 mg/kg/day for a total dose of 1.5 g or more may be useful and previously was considered first-line therapy for all forms of the disease. Fluconazole 400 to 800 mg/day for 6 to 12 months and ketoconazole are alternatives, although the relapse rate may be high. In general, response to treatment is excellent.²³

Paracoccidioidomycosis

Paracoccidioidomycosis (PCM), caused by *Paracoccidioides brasiliensis*, is an endemic disease in the south of Venezuela and Brazil, and armadillos are the natural reservoir.

The disease has a restricted distribution and has been reported only in Latin America from Mexico to Argentina; it does not occur in the Caribbean or any region of the United States, except in travelers to those endemic areas. The primary foci of infection are the lungs through the inhalation of airborne spores, but the disease may affect the skin, colon, genital tract, and central nervous system. This disorder can be classified into an acute/subacute (or juvenile) variety, which accounts for 3% to 5% of all cases, and a chronic (adult) variety, which can be unifocal. The prevalence of bone lesions ranges from 2% to 30%, and articular and muscular involvement are very rare. Osteoarticular involvement is the primary presentation of PCM in up to 42% of cases.

The clinical picture is highly variable. The disease shows a male predominance; affects mostly manual workers, which suggests that exposure is occupation dependent; and ranges from an asymptomatic state to malaise, low-grade fever, lymph node enlargement, and oral ulcers with inflamed lips and deformity (tapir mouth). Pharyngeal, laryngeal, and tracheal involvement may occur. Severe lymphadenitis with swelling and neck deformity (buffalo neck) may be seen. Adrenal insufficiency is occasionally noted, as is involvement of the spleen, liver, gastrointestinal tract, eyes, male genitourinary tract, and central nervous system. Bones commonly affected include the scapula, acromion, clavicle, rib, humerus, radius, and phalanges. Bony lesions produce mild but slowly progressive pain. Most patients have pulmonary involvement (tuberculosis-like infection); therefore, differential diagnoses include other granulomatous conditions such as tuberculosis, sarcoidosis, fungal infections, and malignancies (lymphoma). Radiologic findings include osteolytic lesions, as well as metaphyseal or meta-epiphyseal osteomyelitis of the long bones, which can be solitary or multifocal.²⁵

Diagnosis is difficult, and PCM should be considered in immunocompromised patients from endemic areas. Detection of antigen in cerebrospinal fluid and in bronchoalveolar lavage fluid increases the sensitivity for diagnosis and facilitates monitoring of the response to treatment.

Treatment

Treatment of mild to moderate disseminated PCM infection requires administration of itraconazole 200 mg orally daily for 6 months, or ketoconazole 200 to 400 mg/day orally for 6 months, or sulfadiazine 25 to 50 mg/kg (maximum 1 to 1.5 g/dose) orally in 2 to 4 divided doses daily for 6 to 12 months, as well as surgical intervention if needed. Successful treatment of skeletal disease with trimethoprim-sulfamethoxazole administered for a prolonged period (1 to 4 years) has been reported.

Coccidioidomycosis

Coccidioidomycosis is a self-limited disease caused by *Coccidioides immitis* and *Coccidioides posadasii* present in the soil. Endemic areas have been identified in the southwestern United States (San Joaquin fever, desert rheumatism, and Posada disease), northern Mexico, and Central and South America.

Coccidioidomycosis is primarily a lung disease. Systemic dissemination occurs in about 1% of cases. Risk of infection is related to residence in endemic areas and occupations requiring the frequent aerosolization of soils, such as construction, agriculture, archaeology, and excavation. In addition, high incidence has been reported in Filipinos and African Americans.

The clinical picture in coccidioidomycosis of subacute onset is characterized by cough, shortness of breath, fatigue, pleuritic chest pain and fever (Valley fever), arthralgias, myalgias, rash, erythema nodosum, and erythema multiforme. Musculoskeletal involvement includes monoarthritis (more often the knee) or oligoarthritis in the early stages or osteomyelitis in late stages involving large joints. The spine may also be affected.

One practice reported an incidence rate of coccidioidomycosis of 1.9% and a rate of 3.1% to 3.6% in patients with RA. The annual incidence was 1% in patients recently diagnosed with RA and 2% in patients with recently initiated infliximab treatment.²⁶

Diagnosis requires the presence of an illness consistent with *Coccidioides* infection and one of the following: (1) culture recovery of the organism from an affected site or blood; (2) direct microscopic or histopathologic demonstration of the organism; or (3) demonstration of coccidioidal antibody in cerebrospinal fluid or a two-dilution rise measured in two consecutive blood samples tested.

C. immitis grows readily in culture, and synovial fluid analysis and examination of biopsy tissue samples are also excellent ways to identify the fungus.

Treatment

Symptomatic management for 1 to 2 weeks suffices to control complaints in most patients. Drugs of choice are itraconazole solution 200 mg twice daily orally for 3 to 6 months or fluconazole 400 mg/day orally or IV for many months to years in duration. Extensive or severe disease may require treatment with amphotericin B followed by itraconazole or fluconazole. Surgery may also be required.

Prophylaxis is limited to laboratory workers and those at high risk of inoculation as well as selected patients receiving transplanted organs from donors with known coccidioidal infection.²⁷

Cryptococcosis

Cryptococcosis is worldwide in distribution and is caused by *Cryptococcus neoformans*, which resides in the soil and typically infects via the respiratory tract. Frequent contact with urban-living birds (pigeons, chickens, and parrots), guano, and rotten wood appears to be the mode of infection. More recently, *Cryptococcus gattii* is emerging as an important pathogen in several parts of the world.²⁸

Dissemination is rare and is usually associated with immunosuppression, either iatrogenic or HIV related. Other conditions linked to cryptococcosis include diabetes mellitus, corticosteroid use, malignancies, sarcoidosis, and liver cirrhosis.

The clinical picture of infection is variable and lacks specificity. Mild fever, nonproductive or slightly productive cough, and malaise are frequently seen. Often the disease is restricted to the respiratory tract (90% of cases) with a variety of features, including pulmonary nodules, interstitial pneumonitis, pleural effusions, adenopathy, and acute respiratory distress syndrome. However, any organ, muscle, eye, bone, skin, or mucosa can be affected; the organism has a particular affinity for the central nervous system, and meningitis is the most common clinical manifestation in HIV-associated cryptococcosis.

Musculoskeletal manifestations, including arthritis and osteomyelitis with paravertebral abscess, resemble tuberculosis. Diagnosis is made by isolation of the microorganism from synovial fluid, cerebrospinal fluid obtained by lumbar puncture (with India ink staining), or tissue samples. Recently advances have been made in the use of ELISA, antigen detection (titers), and the random amplified polymorphic DNA technique to detect the fungi. Skeletal radiographs typically show lytic lesions without periostitis.

Treatment

Management requires débridement or drainage. In addition, fluconazole 400 mg/day intravenously or orally for 8 weeks to 6 months in nonmeningeal or non-HIV-associated cryptococcosis is needed. For more severe disease or HIV-related infection, the recommended treatment is amphotericin B 0.5 to 0.8 mg/kg/day intravenously plus flucytosine 37.5 mg/kg every 6 hours orally until the patient becomes afebrile and culture results are negative, and then continuation with fluconazole lifelong therapy.

Aspergillosis

Despite progress in early diagnosis and treatment of aspergillosis, mortality rate remains high. Aspergillosis is caused by several (more than 150) species of ubiquitous and opportunistic fungi. In the United States, *Aspergillus* infection has been estimated to occur at a rate of 12 per 1 million inhabitants per year.

Invasive *Aspergillus* infection is the most common cause of mortality due to invasive mycosis in the United States, with mortality rates ranging from 80% to 95% without treatment and 29.2% and 42.1% after 12 weeks of treatment with voriconazole or amphotericin B, respectively. Stem cell and solid organ transplantation, hematologic malignancy, and intraarticular steroid injection are risk factors.²⁹ The clinical picture may range from a relatively rapid course with inexorable progression to a very slow

and surprisingly indolent course, with the infection appearing to improve temporarily even without treatment. Cough, fever, sinusitis, and asthmalike features are characteristics of allergic pulmonary manifestations. Hemoptysis is noted when an aspergilloma occurs in the lung.

Dissemination is acute and life threatening and usually occurs by (1) contiguous spread from an adjacent involved organ, most commonly the lung; (2) hematogenous spread from a distant focus; and (3) iatrogenic inoculation. Fungi embolism (20% to 50% of cases) allows infection of any organ, including bones, where lytic lesions may be seen. Involvement of the central nervous system (meningitis and abscess) and skin (papules, abscess, plaques, or ulcers) are often related. Musculoskeletal involvement is quite rare, although osteomyelitis and/or vertebral involvement may occur. The knee is the most affected joint, followed by the shoulder. Synovial fluid analysis may show elevated cell count with a predominance of polymorphonuclear neutrophils.³⁰

Diagnosis is difficult to establish, but mycelia can be visualized at times, and the fungus may be cultivated in standard media. Most cases, however, require examination of tissue biopsy samples to identify the fungi. Serologic tests for circulating antigen or antibody using immunodiffusion or ELISA yield positive results in 50% to 70% of cases. Testing for *Aspergillus* galactomannan antigens in serum and PCR testing of serial blood samples in patients at high risk have been suggested.

Treatment

Management varies according to the severity of the infection and includes medical and surgical débridement if aspergilloma is present. Voriconazole 6 mg/kg intravenously twice daily for a day, then 4 mg/kg intravenously for at least 7 days followed by the maintenance dose of 200 mg orally for 8 weeks, is the standard therapy. The second choice is lipid-based amphotericin B, which may be as effective and less nephrotoxic than standard amphotericin B but is much more expensive. There are also other antifungal therapies available, including caspofungin.

Candidiasis

Candidiasis is the fourth most common cause of nosocomial bloodstream infections in the United States and results from disseminated *Candida* infection. There are more than 190 *Candida* species but only eight are important human pathogens: *C. albicans*, *C. guilliermondii*, *C. krusei*, *C. parapsilosis*, *C. stellatoidea*, *C. tropicalis*, *C. pseudotropicalis*, and *C. glabrata*.

C. albicans remains the species most commonly associated with candidemia (50% of cases), followed by *C. glabrata* and *C. parapsilosis*, which are normal commensal organisms in humans, and most disseminated infections are endogenous and originate from the gastrointestinal tract. Colonized indwelling central venous catheters may also serve as a conduit for organisms into the bloodstream.

Neutropenic patients, organ transplant recipients, postsurgical patients, and patients receiving parenteral alimentation, and patients receiving broad-spectrum antibiotics are at higher risk of disseminated candidiasis. Clinical features include fever, malaise, and skin and mucosal involvement. Bone, joint, and cartilage involvement may also occur. *Candida*-associated osteomyelitis occurs most commonly in the spine in adults and the long bones in children. Pain is the most significant complaint.

An isolated monoarthritis may occur caused by direct inoculation of fungi that inhabit the skin, or inoculation by injection or during surgery. The second syndrome is the development of a monoarthritis or polyarthritis as a complication of hematogenous disseminated candidiasis. Costochondral joint involvement may be seen in intravenous drug users. Synovial fluid is inflammatory, with predominantly polymorphonuclear cells. Radiographs or bone scans are used to demonstrate osteomyelitis. MRI is more sensitive and can reveal earlier lesions.

The current gold standard is blood culture (results are negative in 50% of cases). However, combined mannan antigen and antimannan antibody detection assays have demonstrated a sensitivity of 71% to 100% and a specificity of 86% to 93%. In the United States, there is more experience with (1→3)-β-D-glucan detection as a broad-spectrum assay for fungal pathogens. Optimized PCR assays have sensitivities and specificities for candidemia and documented or probable invasive candidiasis that exceed 90%.³¹

Treatment

Intravenous amphotericin B is the drug of choice, 0.6 to 0.7 mg/kg per day IV treatment duration may last 3 to 6 months. Frequent joint aspiration may be needed. Prosthetic joint infections are refractory to treatment and often require removal of the prosthesis.

The mortality from systemic infection has been reported to be as high as 56%. Refractory vertebral osteomyelitis may be treated with antifungal

combinations, and caspofungin, micafungin, or anidulafungin have been recently introduced as alternatives.

Prevention measures are very important to decrease the incidence of this infection, especially diabetes control, surveillance of peripheral catheters, and oral prophylaxis with fluconazole or nystatin in selected immunocompromised patients to avoid gastrointestinal dissemination.

Sporotrichosis

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungus. Sporotrichosis occurs worldwide. Decaying vegetation, soil, wood, and hay are ideal growth environments for this fungus. Traumatic inoculation (skin injury) is the main portal of entry. The disease occurs more frequently in farmers, gardeners, miners, forestry workers, and immunosuppressed hosts. Zoonotic transmission may occur through scratches or bites from rodents, cats, dogs, horses, and armadillos.

Clinical manifestations occur in the skin at the site of inoculation, typically the extremities and more often the hands (fingers) or face, but can be localized on any (exposed) part of the body. Small nodules enlarge progressively and become red, pustular, and ulcerative with release of purulent material. The lymphocutaneous form occurs in 65% to 82% of patients and produces a chain of ulcerative (chancrous) and nodular skin lesions. Typically, the older distal lesions exhibit more ulcerations than younger proximal lesions, with bridges of normal skin between them.

Systemic disease results as a consequence of hematogenous dissemination after spread from a pulmonary focus, the primary inoculation site, or regional lymph nodes. Large joints and large bones may be affected, including the tibia, fibula, knee, elbow, ankle, or wrist. The most common complaints are pain and gradual onset of stiffness. Osteomyelitis is a major concern, with bone destruction and draining fistulas from which the organism is readily cultivated. Erythema nodosum–like lesions may occur as well as tenosynovitis, periostitis, synovial effusion, and osteolysis.

Demonstration of *S. schenckii* is needed for a definitive diagnosis. Serologic agglutination tests are useful for the diagnosis of extracutaneous manifestations. Radiographic findings are nonspecific. Osteopenia, joint space narrowing, or lytic lesions may be seen.

Treatment

The management of sporotrichosis often requires surgical débridement. Itraconazole is the drug of choice for skin, musculoskeletal, or meningeal involvement. A dosage of 200 mg orally twice daily for at least 12 months is needed.

Potassium iodide 1 to 3 g orally three times a day for 2 to 4 months may be successful for cutaneous manifestations. Trimethoprim/sulfamethoxazole, fluconazole, or liposomal amphotericin B also may be used. Prevention measures include avoiding scratches from vegetation or pets and washing and disinfecting wounds immediately.

PARASITIC ARTHRITIS

Musculoskeletal involvement secondary to parasitic infection is an important cause of arthritis in certain geographic areas of the world. This zoonotic disorder is closely related to cultural and dietary habits, such as ingestion of undercooked food containing parasitic agents. Risk factors include immunocompromised states, residence in or travel to an area of epidemic parasitosis, or poor hygienic conditions. Primary parasitic musculoskeletal involvement is rare, and in most cases concomitant involvement of gastrointestinal organs and lungs is seen. Parasites may produce symptoms by direct invasion or induction of autoimmune-mediated reactions. The spectrum of disease is highly variable, ranging from asymptomatic infection to vasculitis, reactive arthritis, large abscesses, or polymyositis. Diagnosis requires a high degree of suspicion in individuals at high risk, those with atypical clinical manifestations, and those with poor response to conventional treatment (Box 108.5).

Diagnosis is facilitated by clinical history and the presence of peripheral eosinophilia, which often correlates with the degree of musculoskeletal involvement. Diagnostic tests should include parasitic, serologic, and molecular assays, with confirmation by histopathologic examination. Radiologic studies are helpful (Table 108.2).

Parasitic infections may be grouped into four subsets: protozoan, cestode, nematode, and trematode.

BOX 108.5 CHARACTERISTICS OF PARASITIC RHEUMATISM

- Inflammatory arthropathy
- Association with residence in or travel to an area of epidemic parasitosis
- Eosinophilia
- Absence of radiologic findings
- No response to antirheumatic treatment
- Identification of parasite
- Response to antiparasitic medications

TABLE 108.2 Musculoskeletal associations and treatment of parasitic infections

Parasite	Musculoskeletal associations	Diagnostic workup	Treatment
Protozoans			
<i>Ameba</i> species	Arthritis: knee, reactive arthritis	Trophozoites and cysts in stool	Metronidazole
<i>Cryptosporidium</i>	Reactive arthritis	Oocysts in stool specimens	TMP/SMX
<i>Giardia intestinalis</i>	Children: polyarthritis related to HLA-B27	Trophozoites and cysts in stool, duodenal biopsy and aspirates, ELISA	Metronidazole or albendazole
<i>Plasmodium</i> species	Myalgia, RA-like manifestations	Blood smear, ELISA, PCR	Chloroquine
<i>Toxoplasma</i> species	Myositis, vasculitis, RA-like manifestations	Tissue biopsy, PCR	Pyrimethamine
<i>Trypanosoma</i> species	Myositis	Blood smear, ELISA	Sulfadiazine
Cestodes			
<i>Echinococcus granulosus</i>	Bone cyst	Bone radiograph, ELISA, Western blot, histopathologic examination	Albendazole, praziquantel
<i>Taenia</i> species	Muscle weakness, palpable nodules	Eggs and proglottids in stool	Praziquantel, niclosamide
Nematodes			
<i>Strongyloides</i> species	Oligoarthritis, vasculitis	Larvae in stool, sputum, or other body fluid	Ivermectin
<i>Dracunculus</i> species (Guinea worm)	Monoarthritis, arthralgias	Calcified worms on radiograph	Mebendazole
<i>Filaria</i> (<i>Loa loa</i>)	Arthralgias, RA-like manifestations	Serologic testing, tissue biopsy	Diethylcarbamazine
Trematodes			
<i>Schistosoma</i> species	ReA-like manifestations, oligoarthritis, RA-like manifestations, sacroiliitis	Schistosome eggs in feces, urine, or biopsy specimen	Praziquantel

ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction; RA, rheumatoid arthritis; ReA, reactive arthritis; TMP/SMX, trimethoprim-sulfamethoxazole.

Protozoans

A variety of protozoans may cause musculoskeletal manifestations, including *Amoeba* species, *Cryptosporidium parvum*, *Cyclospora cayetanensis*, *Isospora belli*, *Sarcocystis* species, *Giardia intestinalis*, *Leishmania* species, *Plasmodium* species, *Microsporidia* species, *Pneumocystis jiroveci*, *Toxoplasma gondii*, *Trypanosoma* species, and *Trichomonas* species.

A wide spectrum of clinical manifestations may occur. *T. gondii* induces a mononucleosis-like illness characterized by fever, cervical adenopathy, myalgias, and malaise. *Trypanosoma cruzi* favors involvement of smooth and striate muscles and causes severe autonomic disturbances in the cardiovascular and gastrointestinal systems. *Microsporidia* and *Entamoeba* infections produce precipitate diarrhea, keratoconjunctivitis, genitourinary infections, hepatitis, and myositis. *Plasmodium* infection commonly causes myalgias and myositis and rarely rhabdomyolysis. Visceral leishmaniasis or kala-azar syndrome manifests with fever, severe cachexia, hepatosplenomegaly, and pancytopenia, and a few cases of myositis or cutaneous dermatomyositis-like lesions have occurred in patients with acquired immunodeficiency syndrome patients.

Musculoskeletal involvement includes polyarthritis or oligoarthritis, RA-like joint involvement, reactive arthritis, polymyositis- or dermatomyositis-like features, and bone cysts. Large bones or joints are often affected, and diarrhea or other gastrointestinal manifestations may occur.

Diagnosis

ELISA and indirect fluorescent antibody testing have been used to establish diagnosis. PCR-based assay and real-time PCR are new tools with a high degree of accuracy. Refractoriness and/or unresponsiveness of diseases to standard therapies should raise suspicion of parasitic infection in endemic areas. Clinical manifestations, serologic tests, and radiologic imaging studies are all useful in identifying parasitosis. However, the diagnosis should be confirmed only by direct identification of the parasitic agent in synovial fluid or biopsy specimens.

Cestodes

Cysticercosis is the most important cestode infection. *Taenia solium* (pork tapeworm), the causative agent, belongs to the intestinal tapeworm group. Musculoskeletal involvement is characterized by muscle weakness and/or palpable nodules. Over 75% of patients with neurocysticercosis also have affected muscles with dot-shaped or ellipsoidal calcifications in the muscle bundle in thighs or arms. Other organisms are *Diphyllobothrium latum* (fish tapeworm), *Hymenolepis nana* (dwarf tapeworm), and *Taenia saginata* (beef tapeworm). In addition, tissue tapeworms such as *Echinococcus granulosus* may infect muscle and large bones.

Musculoskeletal involvement is variable, and symmetric arthritis of the wrists and metacarpophalangeal and proximal interphalangeal joints has been described. Cystic lesions of bone may be seen as manifestations of hydatidosis, in which the spine (30%), pelvis/hip (20%), and femur and tibia (15%) are commonly affected sites.

Diagnosis

Diagnosis of *T. solium* infection requires detection of eggs or proglottids in stool specimens. ELISA can detect live parasites and can be used to guide therapeutic decisions. Infections with *Echinococcus* species (hydatid disease) are a common cause of musculoskeletal involvement. Radiographic findings of bone cysts may support the diagnosis.

Serologic antibody testing and histopathologic examinations (subcutaneous nodules can be excised) are complementary tools to reach a final diagnosis.

Nematodes

A wide spectrum of complaints may be seen with infection by nematodes. Dracunculiasis is caused by *Dracunculus medinensis* and may induce

asymptomatic disease until the worm migrates to the subcutaneous tissue, usually in the lower extremities, where it may induce chronic ulcers with parasitic discharge. Knee monoarthritis (Ibadan knee) and septic and destructive arthritis are seen. Lymphatic filariasis (caused by *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*) and tissue filariasis (dirofilariasis, loiasis, and infection with *Onchocerca volvulus*, which also cause blindness river in Africa and Central and South America) are characterized by a variety of manifestations ranging from acute lymphatic inflammation or chronic lymphatic obstruction—leading to elephantiasis of the extremities, arthritis resembling septic arthritis, swelling, and localized subcutaneous edema—to migratory arthritis.

Infection with *Trichinella* species may involve the muscles, and symptoms are related to the number of larvae ingested (fewer than 10 larvae per gram are often asymptomatic, whereas more than 50 larvae per gram are associated with muscular symptoms) as well as host characteristics such as age, size, and underlying health conditions. Muscle invasion is manifested by myalgias, swelling, and weakness. Myositis of any striate muscle (which may begin with extraocular muscle involvement and diplopia) can develop 5 to 6 weeks after infection, but only 2% of cases are life threatening (due to heart dysrhythmias, pneumonitis, or brain involvement).

Diagnosis

Diagnosis depends on the detection of microfilaria in blood collected at midnight. ELISA and PCR assays are excellent indicators of active nematode infection, but sometimes muscle or tissue biopsy is needed to confirm the diagnosis.³²

Trematodes

Toxocariasis (visceral larva migrans) may also affect muscle or bone tissue; polyarthralgias, monoarthritis or oligoarthritis, and dermatomyositis-like and vasculitis-like features are the major complaints. Infection with *Schistosoma mansoni* and *Schistosoma haematobium* can be associated with arthritis, enteritis, and, occasionally, diffuse myopathy. Katayama syndrome occurs 4 to 8 weeks after exposure to fresh water contaminated with schistosomes and is seen mainly in Africa, South America, and the Arabian peninsula. A serum sickness-like illness with fever, cough, headache, abdominal tenderness, and urticaria are the most remarkable findings. In addition, there can be loss of muscle mass, muscle weakness, involvement of the pelvic diaphragm with rectal prolapse, and reduced physical activity.

Diagnosis

A diagnosis of *Schistosoma* infection is suggested by travel to endemic areas, eosinophilia, and possibly a history of swimmer's itch. Microscopic visualization of eggs in a stool smear, antigen detection by ELISA, and rectal biopsy are very specific diagnostic methods.

A high index of suspicion is needed to diagnose nematode and trematode infection in the setting of musculoskeletal involvement. Serologic tests, radiographic studies, tissue biopsy, and examination of stool specimens are all useful to establish a diagnosis. Furthermore, isolation or demonstration of the specific agent is mandatory to initiate the most effective and specific treatment.

Treatment

Management of parasitic complaints depends on the causal agent. Specific treatment is required most of the time, and symptoms improve following eradication of the parasite. In addition, NSAIDs and surgical intervention may be needed (see Table 108.2). It is important to become familiar with antiparasitic agents and their dosages and potential adverse effects. The Mazzotti reaction (arthralgias, rash, fever, lymphadenopathy, tachycardia, and hypotension) is a relatively common complication related to the treatment of active filariasis and is seen after the use of diethylcarbamazine.

109 Lyme disease

■ ALLEN C. STEERE

- Lyme disease is a tick-borne infection caused by the spirochete *Borrelia burgdorferi* sensu lato leading to a multisystem illness primarily in the skin, joints, nervous system, and/or heart.
- Peak onset of early infection is the summer months in endemic areas in North America, Europe, and Asia.
- The first clinical sign is usually a slowly expanding skin lesion, erythema migrans, which occurs at the site of the tick bite.
- Disseminated infection is often associated with characteristic manifestations in the skin, joints, nervous system, and/or heart.
- In the United States, arthritis in one or a few joints, especially the knee, is the most common late disease manifestation.
- Diagnosis is usually based on characteristic clinical findings and a positive result on an immunoglobulin G serologic test for *B. burgdorferi* by ELISA and Western blot.
- Treatment with oral antibiotic therapy for 1 month is usually successful, but some patients with arthritis or neurologic involvement require intravenous antibiotics.

HISTORY

Lyme disease was recognized as a separate entity in 1976 because of the geographic clustering in Lyme, Connecticut, of affected children, who were thought to have juvenile rheumatoid arthritis.¹ However, parts of the illness were recognized previously in Europe and were given different names, including *erythema chronicum migrans*, *Bannwarth syndrome*, and *acrodermatitis chronica atrophicans*.² These syndromes were linked conclusively in 1982 and 1983 with recovery of a previously unrecognized spirochete from the tick vector³ and from infected patients.⁴ The basic outlines of the disease are similar worldwide, but there are regional variations.⁵ Arthritis is a prominent feature of late infection in the United States.

EPIDEMIOLOGY

Lyme disease occurs in North America, Europe, and Asia (Fig. 109.1). In the United States, the disease is located primarily in three geographic areas: in the northeastern and mid-Atlantic states, in the upper Midwest, and in northern California. However, the infection is spreading to new geographic locations; it is increasing in frequency; and it is epidemic in certain locations in the northeastern states.⁶ Currently, about 30,000 cases are reported yearly to the Centers for Disease Control and Prevention (CDC), but the actual number may be closer to 300,000 cases annually.⁷ The disease may also be acquired in locations throughout Europe, particularly in central Europe, and in Russia, China, and Japan.

The vectors of Lyme disease are 14 closely related ixodid tick species that are part of the *Ixodes ricinus* complex: *Ixodes scapularis* in northeastern and upper Midwestern states, *Ixodes pacificus* on the West coast, *Ixodes ricinus* in Europe, and *Ixodes persulcatus* in Asia.⁶ Ticks of the *I. ricinus* complex have larval, nymphal, and adult stages. In North America and Europe, it is the tiny nymphal tick that is primarily responsible for transmission of the disease during the late spring or early summer months. The tick must usually be attached for at least 24 hours before transmission of the spirochete occurs.

ETIOLOGIC AGENT

The *Borrelia* are loosely coiled, spiral, microaerophilic bacteria (Fig. 109.2). *Borrelia burgdorferi* sensu lato (i.e., *B. burgdorferi* in the general sense) consists of 14 closely related genospecies.⁶ However, the human infection is caused primarily by three genospecies. In the United States, *B. burgdorferi* sensu stricto (*B. burgdorferi* in the strict sense), hereafter referred to as *B. burgdorferi*, is the sole cause of the disease, whereas *Borrelia afzelii* and *Borrelia garinii* are the primary causes in Europe and Asia.

Strains of *B. burgdorferi* have been subdivided according to several typing schemes: one based on sequence variation in outer-surface protein C (OspC), a second based on the 16S-23S ribosomal RNA intergenic spacer region (RST), and a third called *multilocus sequence typing*.⁸ From these typing systems there is emerging evidence that strains of *B. burgdorferi* differ in pathogenicity. OspC type A (RST1) strains, which account for 30% to 50% of the infections in the northeastern United States, are particularly virulent.^{8,9} These strains are thought to have played an important role in the emergence of Lyme disease in epidemic form in the United States in the late 20th century.¹⁰

PATHOGENESIS

To maintain its complex enzootic cycle, *B. burgdorferi* must adapt to two markedly different environments: the tick during the fall, winter, and spring, and the mammalian host during the summer months, where it meets its nutritional requirements.⁶ The spirochete expresses a different set of proteins on its outer membrane in the tick and in the mammalian host. For example, outer-surface protein A (OspA) is expressed primarily in the midgut of the tick, whereas OspC is upregulated as the organism travels to the tick salivary gland. There, OspC binds a tick salivary gland protein (Salp15), which is required for infection of the mammalian host.¹¹

Once in the mammalian host, the spirochete downregulates OspC, and upregulates the VlsE lipoprotein, which undergoes extensive antigenic variation during the course of the infection.¹² Some *Borrelia* strains bind host complement regulator proteins to their surface, which help protect spirochetes from complement-mediated lysis.¹³ During hematogenous dissemination, *B. burgdorferi* surface proteins attach to host integrins, glycosaminoglycans, and glycoproteins.⁶ Finally, spirochetal decorin-binding proteins bind decorin, a glycosaminoglycan on collagen fibrils.¹⁴ This binding may explain why the organism is commonly aligned with collagen fibrils in the extracellular matrix of the heart, nervous system, or joints.

To control and eradicate *B. burgdorferi*, the host mounts both innate and adaptive immune responses, resulting in macrophage- and antibody-mediated killing of the spirochete. Cells at affected sites release potent proinflammatory cytokines, including interleukin-6, tumor necrosis factor- α , interleukin-1 β , and interferon- γ .⁶ Patients who are homozygous for a TLRI (Toll-like receptor 1) polymorphism (1805GG), particularly when infected with highly inflammatory *B. burgdorferi* RST1 strains, have exceptionally high levels of proinflammatory cytokines.¹⁵ The purpose of the adaptive immune response seems to be the production of specific antibodies, which opsonize the organism. This process helps greatly in phagocytosis and effective spirochetal killing.

Within several weeks to months, innate and adaptive immune mechanisms, even without antibiotic treatment, control widely disseminated infection, and generalized systemic symptoms wane. In the absence of antibiotic therapy, however, spirochetes may survive in localized niches for several more years. For example, *B. burgdorferi* infection in the United States may cause persistent arthritis or, in rare cases, a subtle encephalopathy or

Fig. 109.1 The dots show locations affected by Lyme disease in North America, Europe, and Asia.

Fig. 109.2 Scanning electron micrograph of *Borrelia burgdorferi*. The *Borrelia* species are longer and more loosely coiled than the other spirochetes. Of the *Borrelia* species, *B. burgdorferi* is the longest (20 to 30 μm) and narrowest (0.2 to 0.3 μm).

polyneuropathy. Eventually, immune mechanisms seem to succeed in the near or total eradication of *B. burgdorferi* from selected niches, including the joints or nervous system, and in most patients, symptoms resolve.

CLINICAL MANIFESTATIONS

Natural infection, without antibiotic therapy, generally occurs in stages, with different clinical manifestations at each stage.² Early infection consists of stage 1 (localized erythema migrans), followed within days to weeks by stage 2 (disseminated infection, particularly affecting the nervous system or heart), followed within months by late infection (stage 3, persistent infection, particularly affecting joints). However, early infection may be asymptomatic, and the illness may present with stage 2 or 3 manifestations. A complete list of possible manifestations at each stage is given in Table 109.1.

Skin

In approximately 80% of American patients, Lyme disease begins with a slowly expanding skin lesion, erythema migrans, which occurs at the site of the tick bite.¹⁶ As the area around the center expands, most lesions

Fig. 109.3 Erythema migrans. (a) The site of the tick bite is visible near the center of the lesion. (b) Typical bull's-eye lesion. (From Huppertz H-I, Dressler F. Lyme Disease. In: Cassidy J, Petty R, Laxer R, et al, editors. Textbook of pediatric rheumatology. 6th ed. Philadelphia: Saunders; 2011.)

develop bright red outer borders with partial central clearing (Fig. 109.3).^{2,5} The centers of early lesions sometimes become intensely erythematous and indurated, vesicular, or necrotic. In America, erythema migrans is frequently accompanied by nonspecific flulike symptoms such as headache, neck stiffness, myalgias, arthralgias, malaise, or fatigue, and these symptoms, without erythema migrans, may be the presenting picture of the illness.¹⁷ Fever, if present, is typically low grade, except in young children. Malaise and fatigue may be debilitating.

Patients with erythema migrans may be coinfecting with other infectious agents transmitted by the same tick, including *Babesia microti* (a red cell parasite) and *Anaplasma phagocytophilum* (which infects granulocytes).^{18,19} As in early Lyme disease, each of these pathogens may cause nonspecific flulike symptoms during summer, and coinfection with one or both of these agents may lead to more severe, acute illness. However, neither *A. phagocytophilum* nor *B. microti* is known to cause chronic infection, as with untreated *B. burgdorferi* infection.

Erythema migrans is also the most common feature of Lyme borreliosis in Europe.²⁰ In addition, in Europe the infection is associated with several other dermatologic manifestations that may occur later in the illness.²⁰ Borrelia lymphocytoma is a subacute lesion, typically on the ear or breast, that eventually resolves. Acrodermatitis chronica atrophicans is a slowly progressive lesion located on the extensor (acral) surfaces of the extremities, which may result in persistent spirochetal infection over a period of years.

Nervous system

Within weeks, during or shortly after spirochetal dissemination, about 15% of untreated patients in the United States develop objective signs of acute neuroborreliosis.^{2,5} Possible manifestations include lymphocytic meningitis with episodic headache and mild neck stiffness, subtle encephalitis with difficulty with mentation, cranial neuropathy (particularly unilateral or bilateral facial palsy), motor or sensory radiculoneuritis, mononeuritis multiplex, cerebellar ataxia, or myelitis. Particularly in Europe, the first neurologic sign is often radicular pain, which is followed by the development of a pleocytosis in cerebrospinal fluid, but meningeal or encephalitic signs are more often absent.²¹ In children, the optic nerve may be affected because of inflammation or increased intracranial pressure, which may lead to blindness.²² Even in untreated patients, acute neurologic symptoms typically improve or resolve within weeks to months.

TABLE 109.1

Manifestations of Lyme disease by stage*

System [†]	Early infection		Late infection
	Localized, stage 1	Disseminated, stage 2	Persistent, stage 3
Skin	Erythema migrans	Secondary annular lesions Malar rash Diffuse erythema or urticaria Evanescent lesions Lymphocytoma	Acrodermatitis chronica atrophicans Localized scleroderma-like lesions
Musculoskeletal		Migratory pain in joints, tendons bursae, muscle, bone Brief arthritis attacks Myositis Osteomyelitis Panniculitis	Prolonged arthritis attacks Chronic arthritis Peripheral enthesopathy Periostitis or joint subluxations below lesions of acrodermatitis
Neurologic		Meningitis Cranial neuritis, Bell palsy Motor or sensory radiculoneuritis Subtle encephalitis Mononeuritis multiplex Myelitis Chorea Cerebellar ataxia	Chronic encephalomyelitis Subtle encephalopathy Chronic axonal polyradiculopathy
Lymphatic	Regional lymphadenopathy	Regional or generalized lymphadenopathy Splenomegaly	
Heart		Atrioventricular nodal block Myopericarditis Pancarditis	
Eyes		Conjunctivitis Iritis Choroiditis Retinal hemorrhage or detachment Panophthalmitis	Keratitis
Liver		Mild hepatitis	
Respiratory		Nonexudative sore throat	
Kidney		Microscopic hematuria or proteinuria	
Genitourinary		Orchitis	
Constitutional symptoms	Minor	Severe malaise and fatigue	Fatigue

*The staging system provides a guideline for the expected timing of the different manifestations of the illness, but this may vary in an individual case.

[†]The systems are listed from the most to the least commonly affected.From Steere AC. Lyme disease. *N Engl J Med* 1989;321:586-96.

In perhaps 5% or fewer of untreated patients, *B. burgdorferi* may cause chronic neuroborreliosis, sometimes following long periods of latent infection.⁵ In the United States, the typical picture is a subtle axonal polyneuropathy manifested primarily as spinal radicular pain or distal paresthesias²³ and/or a subtle encephalopathy manifested primarily by mild cognitive disturbances.²⁴ Systemic symptoms are minimal, if present at all. In patients with polyneuropathy, electromyograms typically show diffuse involvement of both proximal and distal nerve segments, and those with encephalopathy often have intrathecal production of antibody to the spirochete.

Cardiac system

Within several weeks after disease onset, about 5% of untreated patients have acute cardiac involvement, most commonly fluctuating degrees of atrioventricular block, occasionally acute myopericarditis or mild left ventricular dysfunction, and rarely cardiomegaly or fatal pancarditis.^{2,5} The duration of cardiac abnormalities is usually brief (between 3 days and 6 weeks), and insertion of a permanent pacemaker is not necessary. In Europe, *B. burgdorferi* has been isolated from endomyocardial biopsy specimens of several patients with chronic dilated cardiomyopathy,²⁵ but this complication has not been observed in America.²⁶

Joints

Months after the onset of illness, often following a latent period, about 60% of untreated patients in the United States have intermittent or persistent attacks of joint swelling and pain, primarily in one or a few large joints, especially the knee, during a period of several years (Fig. 109.4).²⁷

Fig. 109.4 The swollen knee of a 9-year-old child with Lyme arthritis. In the United States, affected knees may be very swollen and warm, but not particularly painful. In Europe and Asia, the amount of joint swelling is often less.

TABLE 109.2

Joint and periarticular sites affected in 28 untreated patients with Lyme arthritis

Joints	No. of patients (N = 28)	Periarticular sites	No. of patients (N = 28)
Knee	27	Tendons	
Shoulder	14	Back	9
Ankle	12	Neck	6
Elbow	11	Bicipital	4
Temporomandibular	11	Lateral epicondyle	2
Wrist	10	Lateral collateral	1
Hip	9	De Quervain tenosynovitis	1
Metacarpophalangeal	4	Bursae	
Proximal interphalangeal	4	Prepatellar	4
Distal interphalangeal	4	Subacromial	2
Metatarsophalangeal	4	Infraspinatus	2
Sternoclavicular	1	Olecranon	2
		Sausage digits	2
		Heel pain	2

From Steere AC, Schoen RT, Taylor E. The clinical evolution of Lyme arthritis. *Ann Intern Med* 1987;107:725-31.

However, particularly in earlier episodes, other large or small joints, the temporomandibular joint, or periarticular sites are sometimes affected (Table 109.2). Affected knees may be very swollen and warm (see Fig. 109.4) but not particularly painful. Baker cysts may form and rupture early. Joint involvement may be milder in young children than in older children or adults.²⁸ Joint fluid white cell counts usually range from 10,000 to 25,000 cells/mm³, but cell counts as low as 500 or as high as 100,000 cells/mm³ have been noted.²⁷ Although tests for rheumatoid factor or antinuclear antibodies typically yield negative results, antinuclear antibodies in low titer may be detected.

Although most patients with Lyme arthritis respond to recommended antibiotic therapies, a small percentage of patients have persistent synovitis for months or several years after receiving oral and intravenous antibiotic therapy for 2 or 3 months, called *antibiotic-refractory arthritis*.²⁹ Rather than persistent infection, infection-induced autoimmunity,³⁰ retained spirochetal antigens,³¹ or both may play a role in this outcome. Antibiotic-refractory arthritis is associated with specific HLA-DR alleles (such as the DRB1*0101 and 0401 alleles),³² a TLR1 polymorphism (1805GG) that leads to exceptionally high levels of cytokines and chemokines in affected joints,¹⁵ and low frequencies of FoxP3+ regulatory T cells in synovial fluid, which correlate with longer posttreatment durations of arthritis.³³ A novel human autoantigen, endothelial cell growth factor, was recently identified as a target of T- and B-cell responses in patients with Lyme disease, which provides the first direct evidence for autoimmune T- and B-cell responses in this illness.³⁰ Synovial histologic findings in these patients, which include synovial hypertrophy, vascular proliferation, and mononuclear cell infiltration, are similar to those in all forms of chronic inflammatory arthritis, including rheumatoid arthritis.³⁴ However, synovial tissue from patients with antibiotic-refractory arthritis often shows obliterative microvascular lesions, which are not found in other types of arthritis.

DIAGNOSIS

Culture of *B. burgdorferi* from patient specimens permits definitive diagnosis.³⁵ However, positive culture results have been obtained mainly early in the illness, primarily from biopsy specimens from erythema migrans skin lesions. Although it is almost impossible to culture *B. burgdorferi* from synovial fluid in patients with Lyme arthritis, polymerase chain reaction testing of synovial fluid for *B. burgdorferi* DNA often yields positive results before antibiotic therapy.³⁶ Even at that time, however, *B. burgdorferi* in synovial fluid appear to be moribund or dead, yet *B. burgdorferi* DNA may also persist after spirochetal killing with antibiotics. For these reasons, detection of *B. burgdorferi* DNA in joint fluid is not an accurate test of active

BOX 109.1 DIAGNOSIS OF LYME DISEASE

- Recognition of a characteristic clinical picture
- Positive antibody response to *Borrelia burgdorferi* determined by a two-test approach using enzyme-linked immunosorbent assay and Western blot analysis, except in patients with erythema migrans
- Interpretive criteria of the Centers for Disease Control and Prevention for Western blot results:
First 30 days of symptoms—two of the following three immunoglobulin M bands: 23, 39, 41 kDa
At any time in the illness—five of the following ten immunoglobulin G bands: 18, 23, 28, 30, 39, 41, 45, 58, 66, 93 kDa

Adapted from recommendations made by the Centers for Disease Control and Prevention.³⁷
From Steere AC. Lyme disease. *N Engl J Med* 2001;345:115-25.

joint infection in Lyme disease and cannot be used reliably to determine the adequacy of antibiotic therapy.

Because of the limited utility of microbiologic techniques, diagnosis is usually based on recognition of a characteristic clinical picture and, except in patients with erythema migrans, a positive antibody response to *B. burgdorferi*. For serologic testing in the United States, the CDC currently recommends a two-test approach in which samples are first tested by enzyme-linked immunosorbent assay (ELISA) and those with equivocal or positive results are tested by Western blotting, with findings interpreted according to the CDC criteria (Box 109.1).³⁷

During the first several weeks of infection, only 20% to 30% of patients with erythema migrans have positive responses in tests of acute-phase samples, usually of the immunoglobulin M (IgM) isotype, but by convalescence 2 to 4 weeks later, 70% to 80% show IgM reactivity, even after antibiotic therapy.^{38,39} After 4 to 8 weeks, patients with active infection have IgG antibody responses to five or more spirochetal proteins, which is required for a positive test result.^{39,40} In persons with infection of longer than 4 to 8 weeks' duration, a positive IgM test result alone is likely to be a false-positive response or one indicative of previous, early infection, and thus a positive IgM response by itself should not be used to support the diagnosis of Lyme arthritis or other late disease manifestations. Patients with Lyme arthritis typically have the highest IgG antibody responses seen in the infection, with expansion of the response to many spirochetal proteins.³⁹ When microarrays of more than 1200 spirochetal proteins were used, 120 proteins, primarily outer-membrane lipoproteins, were found to be immunogenic, and patients with Lyme arthritis had IgG reactivity to as many as 89 of these proteins.⁴¹

The most promising second-generation serologic test is an IgG ELISA that employs a 26-mer peptide of the sixth invariant region of the VlsE lipoprotein of *B. burgdorferi*, called the *C6 peptide ELISA*.^{39,42} Similar results were obtained with this test and the standard two-test approach of sonicate IgM and IgG ELISA and Western blot, and therefore the C6 ELISA has been considered for use as a stand-alone test.⁴³ The principal advantage of the C6 peptide ELISA is the early IgG response, and therefore determination of an IgM response is not necessary. However, the C6 ELISA is not quite as specific as sonicate Western blotting.^{43,44} Therefore, with current methods, a two-test approach that employs sonicate and VlsE ELISAs⁴⁴ or that uses an ELISA and Western blot analysis^{39,40} remains valuable for specificity, and blotting can be helpful in assessing the duration of current or past disease.

After successful antibiotic treatment, antibody titers decline slowly, but responses may persist for many years after treatment,⁴⁵ including responses to the VlsE C6 peptide.¹⁹ Moreover, not only the IgG but also the IgM response may persist for years after therapy. Therefore even a positive IgM response cannot be interpreted as showing recent infection or reinfection unless the appropriate clinical picture is present. Reinfection may occur in patients who were treated for erythema migrans,⁴⁶ but in patients who previously had Lyme arthritis, this seems to occur rarely, if at all. Thus the expanded immune response of late infection appears to protect against reinfection, whereas the incompletely developed immune response of early infection does not.

Differential diagnosis

Lyme arthritis typically causes marked joint swelling and pain in one or a few joints at a time with minimal systemic symptoms.²⁷ This clinical picture is most like reactive arthritis in adults or pauciarticular juvenile idiopathic arthritis in children. Lyme arthritis does not cause chronic, sym-

metric polyarthritis, and therefore distinguishing Lyme arthritis from rheumatoid arthritis is not difficult.

Fibromyalgia and chronic fatigue syndrome are sometimes misdiagnosed as Lyme disease.⁴⁷⁻⁴⁹ In contrast with Lyme arthritis, which causes minimal systemic symptoms, patients with fibromyalgia often have marked fatigue, severe headache, diffuse musculoskeletal pain, stiffness and pain in many joints, diffuse dysesthesias, difficulty with concentration, and sleep disturbance. On physical examination, such patients have multiple symmetric tender points in characteristic locations, but they lack evidence of joint inflammation.

TREATMENT

All manifestations of Lyme disease are usually treated successfully with oral or intravenous (IV) antibiotic therapy for 2 to 4 weeks, depending on the manifestation, as recommended by the Infectious Diseases Society of America (Box 109.2).^{50,51} For early localized or disseminated infection, doxycycline for 14 to 21 days is recommended in persons older than 8 years of age, except in pregnant women. Amoxicillin, the second-choice alternative, should be used in children or pregnant women. Because maternal-fetal transmission of *B. burgdorferi* seems to occur rarely, if at all,⁵² standard

therapy for the manifestation of the illness is recommended in pregnant women.

For patients with objective neurologic abnormalities, 2- to 4-week courses of IV ceftriaxone are most commonly given.⁵⁰ Objective evidence of relapse is rare after a 4-week course of therapy. In Europe, oral doxycycline is often adequate therapy for acute neuroborreliosis,^{53,54} but in the United States, patients with neuroborreliosis may require IV antibiotic therapy for successful treatment of the infection. In patients with high-degree atrioventricular nodal block (PR interval of longer than 0.3 sec), IV therapy for at least part of the treatment course and cardiac monitoring are recommended.⁵⁰ Once the patient's condition has stabilized, the course may be completed with oral therapy.

Lyme arthritis can often be treated successfully with a 30-day course of oral doxycycline or amoxicillin.⁵⁵ However, some patients require 2 to 4 weeks of IV antibiotics for successful treatment of the infection.²⁹ Despite therapy with 2 months or more of oral antibiotics and 1 month or more of intravenous antibiotics, a small percentage of patients in the United States have persistent, proliferative synovitis, primarily in one knee, for months or several years after antibiotic therapy.²⁹ After oral and IV antibiotic therapy, the authors treat such patients with nonsteroidal antiinflammatory agents and/or disease-modifying antirheumatic drugs, such as hydroxychloroquine or methotrexate. If the response to these agents is incomplete, arthroscopic synovectomy may be successful. An algorithm for the treatment of Lyme arthritis is shown in Figure 109.5.

BOX 109.2 TREATMENT AND VACCINATION REGIMENS FOR LYME DISEASE*

Early infection (local or disseminated)

Adults

Doxycycline 100 mg orally twice daily for 14 to 21 days

Amoxicillin 500 mg orally 3 times daily for 14 to 21 days

Alternatives in case of doxycycline or amoxicillin allergy:

Cefuroxime axetil 500 mg orally twice daily for 14 to 21 days

Erythromycin 250 mg orally 4 times daily for 14 to 21 days

Children (age 8 and younger)

Amoxicillin 250 mg orally 3 times daily or 50 mg/kg/day in 3 divided doses for 14 to 21 days

Alternatives in case of penicillin allergy:

Cefuroxime axetil 125 mg orally twice daily or 30 mg/kg/day in 2 divided doses for 14 to 21 days

Erythromycin 250 mg orally 3 times daily or 30 mg/kg/day in 3 divided doses for 14 to 21 days

Neurologic abnormalities (early or late)

Adults

Ceftriaxone 2 g IV once daily for 14 to 28 days

Cefotaxime 2 g IV every 8 hr for 14 to 28 days

Na penicillin G 3.3 million U IV every 4 hr for 14 to 28 days

Alternative in case of ceftriaxone or penicillin allergy:

Doxycycline 100 mg orally 3 times daily for 30 days, but this regimen may be ineffective for late neuroborreliosis

Facial palsy alone: oral regimens may be adequate

Children (age 8 and younger)

Ceftriaxone 75 to 100 mg/kg/day (maximum, 2 g) IV once daily for 14 to 28 days

Cefotaxime 150 mg/kg/day in 3 or 4 divided doses (maximum, 6 g) for 14 to 28 days

Na penicillin G 200,000 to 400,000 U/kg/day in 6 divided doses for 14 to 28 days

Arthritis (intermittent or persistent)

Oral regimens listed above for 30 to 60 days or

IV regimens listed above for 14 to 28 days

Cardiac abnormalities

First-degree AV block: oral regimens, as for early infection

High-degree AV block (PR interval of >0.3 sec): IV regimens and cardiac monitoring

Once the patient's condition has stabilized, the course may be completed with oral therapy.

Pregnant women

Standard therapy for manifestation of the illness. Avoid doxycycline.

AV, atrioventricular; IV, intravenously.

*Antibiotic recommendations are based on the guidelines of the Infectious Diseases Society of America.⁵⁰

POST-LYME DISEASE SYMPTOMS

After antibiotic therapy, some patients have persistent subjective symptoms—primarily pain, neurocognitive symptoms, or fatigue.⁵⁰ Although the frequency of such symptoms decreases with time, perhaps 10% of patients with erythema migrans have symptoms for at least 6 months after treatment,⁵⁶ and the frequency may be greater after disease with neurologic involvement.⁵⁷ Patients with Lyme arthritis usually have minimal, if any, associated symptoms, and subjective symptoms occur rarely after treatment of this manifestation.

Regardless, these subjective symptoms do not appear to respond to further antibiotic therapy. In the largest study of antibiotic therapy for post-Lyme disease symptoms, patients received IV ceftriaxone for 30 days followed by 60 days of oral doxycycline or IV and oral placebo for the same duration.⁵⁸ Six months after starting therapy, the numbers of patients who worsened, stayed the same, and improved were similar in both study groups, which suggests that such symptoms were not a result of persistent infection.

This issue has become more complicated because of patient-advocacy groups that promote months or years of antibiotic therapy for “chronic Lyme disease.” Moreover, chronic Lyme disease has become a common diagnosis for medically unexplained pain or fatigue symptoms, even when there is little or no evidence of previous *B. burgdorferi* infection.^{59,60} Even so, these patients are said to have persistent infection that can be suppressed only with months or years of antibiotic therapy. Although *B. burgdorferi* infection may persist for years in untreated patients, the weight of evidence is against persistent infection as the explanation for persistent symptoms in antibiotic-treated patients with Lyme disease.^{50,51}

PREVENTION

Personal protective measures against tick bites, particularly during the late spring and early summer, may help in the prevention of Lyme disease. Insecticides containing DEET (*N,N*-diethyl-*meta*-toluamide) effectively deter ticks, and tick checks after outdoor exposures are important. Because 24 to 72 hours of tick attachment is necessary before transmission of the spirochete occurs, removal of a tick within 24 hours of attachment is usually sufficient to prevent Lyme disease. However, if an engorged nymphal *I. scapularis* tick is found, a single 200-mg dose of doxycycline usually prevents Lyme disease when given within 72 hours after the tick bite occurs.⁶¹

For people living in areas where Lyme disease is endemic, it has been difficult to keep up these personal protective measures throughout the tick transmission season. For these individuals, vaccination would probably be the most effective approach for prevention of the infection. A safe and effective vaccine was marketed for Lyme disease from 1998 through 2002,³⁵ but it was removed from the market, primarily because of the risk of lawsuits. Nevertheless, experience gained in the 1990s proved the feasibility of this approach.

Fig. 109.5 Algorithm for the diagnosis and treatment of arthritis associated with Lyme disease. DMARDs, disease-modifying antirheumatic drugs; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin; IV, intravenous; NSAIDs, nonsteroidal antiinflammatory drugs; PCR, polymerase chain reaction.

Rheumatologic aspects of viral infections

■ DIMITRIOS VASSILOPOULOS ■ LEONARD H. CALABRESE

HUMAN IMMUNODEFICIENCY VIRUS

- A variety of autoimmune-like and rheumatic manifestations, including arthritis, myositis, Sjögren-like syndrome, vasculitis, and low bone mineral density (BMD), have been described in patients with human immunodeficiency virus (HIV) infection.
- Arthritic syndromes that may be associated are reactive arthritis, psoriatic arthritis, and idiopathic articular disease.
- Associated myopathies includes polymyositis, noninflammatory myopathies, and drug-induced muscle disease.
- Vasculitic disease represents the spectrum of vascular inflammation.
- Sjögren-like disease is characterized by sicca symptoms, diffuse lymphocytic infiltration in the absence of specific autoantibodies.
- Low BMD and fragility fractures are increasingly recognized in aging HIV-infected patients.

OTHER VIRUSES

- A host of different viruses may cause arthritis through various pathogenetic mechanisms, including direct infection of synovial cells, immune complex formation, disruption of cell homeostatic mechanisms, and others.
- The most common arthritogenic viruses in North America and Western Europe are parvovirus B19, and hepatitis B and C viruses, whereas a variety of mosquito-borne viruses (mainly alphaviruses) cause epidemics of polyarthritis in Africa, the western Pacific, and South America.
- The majority of virally caused arthritides are acute, self-limiting illnesses, usually accompanied by fever, distinctive cutaneous manifestations, hematologic abnormalities (especially in parvovirus B19 infection), and other clinical features.
- Chronic polyarthritis mimicking rheumatoid arthritis may occur, especially in patients with chronic hepatitis C infection.
- Diagnosis requires knowledge of the epidemiology of these viral infections and the specific laboratory tests required for the detection of the specific arthritogenic virus.

INTRODUCTION

Despite the high frequency of acute and chronic viral infections worldwide, clinically significant rheumatic manifestations including arthritis and systemic rheumatic disorders occurring during the course of such infections are relatively rare. Viruses can cause either acute self-limited inflammatory polyarthritis (hepatitis B virus [HBV], parvovirus B19, rubella virus) or chronic arthritis (hepatitis C virus [HCV], human immunodeficiency virus [HIV], human T-cell lymphotropic virus type I [HTLV-I]). More recently, epidemics of virus-associated arthritides have been reported in certain areas of the world (Southeast Asia) as well as in travelers from these areas (alphavirus infections), which emphasizes their significance from a public health perspective.

Virus-associated rheumatic syndromes can be challenging both diagnostically and therapeutically. Diagnostically, certain virus-associated rheumatic syndromes can mimic rheumatic diseases such as rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), or Sjögren syndrome. Therapeutically,

administering immunosuppressive therapy to patients with certain chronic viral infections such as HBV or HIV infection can be detrimental to the host.

HUMAN IMMUNODEFICIENCY VIRUS

Since the early 1980s rheumatic complications of HIV infection have been well described (Box 110.1). A number of discrete rheumatic syndromes have been reported,¹⁻³ including reactive arthritis, psoriatic arthritis (Fig. 110.1), HIV-associated arthritis (Fig. 110.2), and others, as well as a number of connective tissue diseases such as diffuse infiltrative lymphocytosis syndrome (DILS) and vasculitis. Since the introduction of active antiretroviral therapy (ART) in 1997, there has been a remarkable transformation not only in the natural history of HIV infection itself but also the attendant rheumatic complications. By contrast, in much of the developing world, access to ART is nonexistent or minimal, and thus HIV and its rheumatic complications have continued unabated.

Rheumatic manifestations in the era before active antiretroviral therapy

In the early 1980s a number of groups described an array of nonsuppurative rheumatic complications in HIV infection, including severe forms of reactive arthritis, psoriatic arthritis, and several nosologically unclear articular syndromes, all of which were clinically challenging (see Box 110.1).³ A variety of connective tissue diseases were described, including numerous forms of vasculitis, inflammatory myopathies, and DILS. The pathogenesis of these disorders has remained unclear with regard to their relationships to the underlying retroviral infection, the immunodeficiency state, or some opportunistic infective complication. Longitudinal studies of HIV-infected patients with inflammatory arthritis demonstrated an increased incidence of arthritis in those with severe or progressive disease.^{3,4} Patients with highly symptomatic rheumatic complications posed profound challenges in management because these complications often occurred in the setting of advanced immunodeficiency in the absence of any effective forms of treatment. The early experience with such patients documented rapid progression to end-stage HIV disease with antirheumatic therapy such as methotrexate. Similarly, clinical anecdotes described patients with idiopathic forms of connective tissue disease such as RA or SLE who experienced spontaneous remission with advancement of the underlying immunodeficiency.⁵

Rheumatic complications in global areas without access to active antiretroviral therapy

Since the early phases of the epidemic in areas such as sub-Saharan Africa, an increased incidence of a number of rheumatic syndromes, including reactive arthritis, spondyloarthritis, and enthesopathies, have been well described. This is particularly interesting because of the nearly complete lack of HLA-B*27 in these African populations. Investigations have demonstrated alternative genetic risk markers. In a series of studies in Zambia, HLA-B*5703 has been demonstrated to be a protective allele against the progression of HIV infection while possibly influencing the increased incidence of spondyloarthritis observed in this population.^{6,7}

A unique vasculopathy involving extracranial (carotid, aorta, and their branches) or intracranial (branches of the circle of Willis) blood vessels has been described in HIV patients over the last decade, initially in South Africa but recently in other areas of the world, and has been termed *HIV-associated vasculopathy*.⁸⁻¹¹ The vasculopathy is characterized by fusiform aneurysms that frequently lead to vascular occlusion and to a number of clinical syndromes such as stroke or ischemia of the upper or lower limbs.¹¹ Although

Fig. 110.2 Hands of a 35-year-old man with advanced human immunodeficiency virus infection fulfilling the American College of Rheumatology criteria for rheumatoid arthritis.

in certain cases arterial wall inflammation has been documented (especially in the periadventitial or vasa vasorum vessels), in other cases no evidence of vasculitis has been found.^{9,11} The diagnosis of HIV-associated vasculopathy is usually made by imaging studies of the affected vessels (computed tomographic angiography, magnetic resonance angiography, invasive angiography) after opportunistic infections or neoplasms of the blood vessels

have been excluded.¹¹ It should be emphasized that patients with HIV infection have also a higher risk of accelerated atherosclerosis of the large vessels, which could be due to the HIV infection itself, traditional cardiovascular risk factors (e.g., dyslipidemia, smoking, diabetes, insulin resistance), or certain antiretroviral drugs.^{12,13}

Rheumatic manifestations in the era of active antiretroviral therapy

Since 1997 with the introduction of ART the frequency of opportunistic infections and many other attendant complications has diminished dramatically. Many of the nonsuppurative rheumatic manifestations and certain connective tissue diseases, including DILS,¹⁴ that were relatively common in HIV patients in the pre-ART era have nearly disappeared.^{2,15}

At the same time, other complications have arisen as a consequence of ART, including numerous metabolic disorders such as lipodystrophy, osteomalacia, and osteonecrosis.³ Low bone mineral density and fragility fractures are increasingly diagnosed in HIV-infected patients.¹⁶ The cause of osteoporosis is multifactorial and includes uncontrolled HIV infection (low CD4 count and/or high HCV RNA levels), antiretroviral therapy (during the first year of treatment, mainly with tenofovir),¹³ and traditional osteoporosis risk factors such as low body mass index, low vitamin D levels, and tobacco and alcohol use.¹⁶ The population of HIV patients is gradually aging, so primary care providers should be aware of this association and screen and treat these patients appropriately in collaboration with HIV specialists.^{16,17}

A peculiar nonsuppurative immune reconstitution syndrome has also been described in patients with advanced immunodeficiency, who, when started on ART, experience either an exacerbation of a previously quiescent or occult rheumatic disease or the *de-novo* appearance of a new rheumatic disease. Disorders that have been described as immune reconstitution syndromes include RA-like disorders, SLE, autoimmune thyroid disease, inflammatory myopathy, and sarcoidosis.¹⁵ Unlike patients in the pre-ART era who demonstrated intolerance to immunosuppressive drugs, patients receiving ART with good CD4 cell counts and well-controlled viral loads appear to tolerate aggressive immunosuppressive therapy, including treatment with biologic agents such as tumor necrosis factor (TNF) inhibitors.^{18,19} Given that even in the industrialized West an estimated one-third of HIV-infected patients remain undiagnosed, clinical vigilance appears warranted, and more widespread testing even in the absence of defined high-risk status has been recommended.²⁰

PARVOVIRUS B19

Virology

Parvovirus B19 was discovered in 1975 and is a member of the Parvoviridae family. Parvovirus B19 is among the smallest viruses known to infect mammalian cells; it is 22 to 24 nm in diameter and consists of an unencapsulated single strand of DNA of 5596 nucleotides.²¹ Parvovirus B19 replicates in erythrocyte precursors after binding to its cognate receptor, the blood group P antigen or globoside. The P antigen is expressed by a variety of cells, including erythrocytes, erythroblasts, megakaryocytes, endothelial cells, hepatocytes, and cardiac cells. The presence of the P antigen alone is not adequate for infection, and a coreceptor is required in the form of $\alpha_5\beta_1$ integrin, which provides an explanation for specific patterns of infectivity.²²

Parvovirus B19 infections occur in outbreaks and are transmitted by respiratory secretions, often in the late winter and spring. Serologic evidence of immunologic memory of parvovirus B19 is common in the form of specific immunoglobulin G (IgG) antibodies and is present in 50% to 70% of the population.²¹ Among immunologically naive individuals, schoolteachers, day care workers, pediatric nurses, and those proximate to small children are highly susceptible.²¹ During outbreaks the household transmission rate of parvovirus B19 can be as high as 50%.

Clinical manifestations

Parvovirus B19 is responsible for a number of clinical syndromes, including the common childhood exanthema erythema infectiosum, or fifth disease, with its classical presentation of a febrile child with a “slapped cheek” appearance and a maculopapular or reticular rash.²¹ Infection during early pregnancy results in the syndrome of fetal hydrops. In adults, parvovirus B19 infection may result in a transient aplastic crisis with chronic anemia as observed in immunocompromised individuals.²¹

The rheumatic manifestations of parvovirus B19 infection are numerous.^{21,23} Articular manifestations of parvovirus B19 infection are uncommon

in children but quite common in adults. Symptoms begin in a few joints and may spread in additive fashion, giving an RA appearance, and often include prominent morning stiffness. Synovitis is minimal, and frank joint effusion is rare. Articular manifestations are most prominent in the early stages of the infection coinciding with the appearance of IgM antibodies during the intense phase of viremia, which suggests an immune complex mechanism. Further complicating the clinical presentation is the documented ability of parvovirus B19 to induce a spectrum of autoantibodies, often transient, including rheumatoid factor (RF), antinuclear antibodies (ANAs), anti-DNA, anti-ENA, antiphospholipid antibodies, and others. In the presence of polyarthritis, autoantibodies, and cytopenias the infection can mimic SLE. The pathogenic mechanism of autoantibody formation is not clear, but recent evidence has provided strong evidence for molecular mimicry.²² Parvovirus B19 has also been associated with a variety of other autoimmune syndromes, including systemic vasculitis, reactive arthritis, Sjögren syndrome, idiopathic inflammatory myopathies, and scleroderma.^{21,23} Systematic search strategies for serologic or *in situ* evidence of parvovirus B19 in patients with RA and vasculitis have revealed no difference in detection rates compared with control subjects without autoimmune disease.²²

Laboratory investigation

The laboratory detection of parvovirus B19 infection depends on identification of specific IgM antibodies with or without the presence of IgG anti-B19. The presence of IgG alone is common and consistent with past infection. IgM antibodies may persist for weeks to months. The virus can also be detected early by polymerase chain reaction assay, although this is not clinically necessary. The critical clinical point regarding parvovirus B19 infection is not to confuse it with idiopathic autoimmune disease and thus to spare the patient unnecessary immunosuppression, because treatment for parvovirus B19 infection is generally supportive. The diagnosis of parvovirus B19 infection must start with a high index of suspicion in an immunologically vulnerable host and must be confirmed by appropriate serologic testing. Routine screening of patients with early inflammatory arthritis is not recommended in the absence of clinical suspicion, because parvovirus B19 is an uncommon cause (0.25% of cases in a recent French study).²⁴

HEPATITIS B VIRUS

Virology

Chronic HBV infection remains one of the most common chronic viral infections, with approximately 350 million people infected worldwide.^{25,26} It is caused by HBV, a hepatotropic, enveloped, double-stranded DNA virus that is transmitted parenterally, sexually, or vertically (mother to child). Chronic HBV infection is most often the result of vertical, perinatal, or early childhood transmission; in adults exposure to the virus after parenteral or sexual transmission most frequently leads to acute hepatitis and viral clearance.^{25,26}

Clinical manifestations

Arthritis in patients with HBV infection can be seen in two different settings: as arthritis related directly to the viral infection (polyarthritis during acute hepatitis B or arthritis in patients with HBV-associated medium-vessel vasculitis or polyarteritis nodosa [PAN]) and as a coexisting arthropathy like RA, SLE, and so on, in patients with chronic HBV infection.⁵

HBV-related rheumatic manifestations are attributed to the deposition of immune complexes containing viral antigens (hepatitis B surface antigen [HBsAg], hepatitis B e antigen [HBeAg]) and antibodies directed against these antigens (anti-HBs, anti-HBe) in the synovium or in vessel walls, which results in arthritis or vasculitis (affecting small or medium-sized vessels).

During the preicteric phase of acute hepatitis B, a small proportion of patients develop a symmetric polyarthritis resembling RA that affects mainly the proximal interphalangeal joints, knees, and ankles.²⁷ Associated symptoms include rash (maculopapular, urticarial, petechial), fever, malaise, and myalgias. In 25% of cases RF is present, whereas C3 and C4 levels are low in approximately 40%. The presence of HBsAg, highly elevated levels of aminotransferases (aspartate aminotransferase [AST], alanine aminotransferase [ALT]), and IgM anti-HBe antibodies provide the definitive diagnosis of HBV-associated polyarthritis and differentiate it from other forms of acute inflammatory polyarthritis. No treatment is needed because the arthritis resolves spontaneously after 2 to 3 weeks.

HBV-associated PAN is a rare form of vasculitis of medium-sized vessels the frequency of which is gradually decreasing worldwide.²⁸ Usually HBV-associated PAN develops during the first 6 months after acute HBV infection, and its clinical presentation and course do not differ significantly from those of classical PAN.²⁸ The most common musculoskeletal manifestations are arthralgias (approximately 50% of cases) and myalgias, whereas frank arthritis, affecting predominantly large joints (knees, ankles, wrists), is observed only in a small proportion of patients.²⁸ HBV-associated PAN has a more severe course with more frequent nerve, gastrointestinal, and heart involvement than non-HBV-associated PAN, but skin involvement appears to be less frequent (approximately 35%). The management of HBV-associated PAN includes treatment with immunosuppressive drugs (corticosteroids, cyclophosphamide in severe cases) and antiviral agents (oral nucleoside or nucleotide analogues). The overall long-term mortality rate of HBV-associated PAN is high (approximately 34%) with a 10-year survival rate of 54%.²⁸ For patients who achieve remission after therapy, however, the overall prognosis is favorable with only 10% of patients experiencing relapse.²⁸

Over the last decade HBV reactivation has been described in patients with chronic rheumatic diseases and coexisting HBV infection after the use of biologic agents such as TNF inhibitors, rituximab, and abatacept in the absence of appropriate antiviral prophylaxis.²⁶ Therefore screening for HBV infection (HBsAg, anti-HBc, anti-HBs) is recommended in patients with rheumatic diseases before the initiation of immunosuppressive therapies, especially treatment with biologic agents. Patients with chronic HBV infection (HBsAg+) should receive oral antiviral therapy (preferably with the newer antiviral agents like tenofovir and entecavir) for the duration of immunosuppressive therapy.²⁶ Patients with past HBV infection (HBsAg−/anti-HBc+) should be monitored regularly with measurement of ALT, HBsAg, and HBV DNA levels and treated with antivirals if there is evidence of HBV reactivation (HBsAg+ and/or HBV DNA+).²⁶

HEPATITIS C VIRUS

Chronic HCV infection is another common chronic viral infection, with more than 180 million people affected worldwide. HCV is an RNA hepatotropic virus that is transmitted parenterally, mainly through injection drug use.^{26,29} Patients who received blood transfusions before 1992 and persons with multiple sexual partners are also at increased risk.^{26,29} In contrast to HBV exposure, the majority of adults exposed to HCV (60% to 85%) develop chronic infection.^{26,29}

Clinical manifestations

The rheumatic manifestations in patients with chronic HCV infection can be divided into four groups (Box 110.2): a coexistent arthritis (not related to HCV infection), arthritis in the setting of HCV-associated cryoglobulinemic vasculitis, arthritis directly related to HCV infection (HCV-associated arthritis), and arthritis induced by antiviral therapy (interferon- α [IFN- α]).³⁰

Coexistent arthropathy

Coexistent arthropathy probably is the most common cause of rheumatic manifestations in patients chronically infected with HCV.⁵ The coexistence of another inflammatory (RA, SLE, Sjögren syndrome, etc.) or noninflammatory (fibromyalgia) arthropathy in this setting creates diagnostic as well as therapeutic problems. These coexisting rheumatic disorders can present with clinical and laboratory features that are also seen in chronic HCV infection, such as sialadenitis, fatigue, positivity for RF and/or ANAs, cytopenias, or low levels of complement (particularly C4). The presence of characteristic laboratory results (anti-cyclic citrullinated peptide [anti-CCP] for RA, anti-double-stranded DNA for SLE, anti-Ro/La for Sjögren syndrome) or radiologic findings (erosive changes in RA) are extremely helpful for the differential diagnosis.

BOX 110.2 ARTHRITIS IN THE SETTING OF HEPATITIS C VIRUS (HCV) INFECTION

- Coexistent arthropathy (rheumatoid arthritis, systemic lupus erythematosus, Sjögren syndrome, fibromyalgia)
- HCV-associated arthritis
- Arthritis in the setting of HCV-associated cryoglobulinemic vasculitis
- Arthritis induced by antiviral therapy (interferon- α)

Fig. 110.3 Cutaneous manifestations in hepatitis C virus–associated cryoglobulinemic vasculitis. (a) Palpable purpura. (b) Confluent purpura. (c) Necrotic ulcers. (From Vassilopoulos D, Calabrese LH. Hepatitis C virus infection and vasculitis. Implications of antiviral and immunosuppressive therapies. *Arthritis Rheum* 2002;46:585-97.)

In terms of treatment of the coexistent rheumatic disorder, especially when long-term immunosuppressive therapy with potentially hepatotoxic medications (methotrexate, leflunomide) is planned, a thorough baseline assessment of the underlying liver disease in collaboration with an experienced hepatologist is imperative.³¹ In patients with advanced liver disease (advanced fibrosis in liver biopsy specimens or decompensated cirrhosis [ascites, encephalopathy, coagulopathy]), medications such as methotrexate or leflunomide should be avoided.³² In patients with less advanced disease and stable liver function, these medications can be used with close monitoring of liver function. With regard to biologic agents such as TNF inhibitors and rituximab, a number of recent studies have demonstrated their short-term safety in rheumatic patients chronically infected with HCV.²⁶

Hepatitis C virus–associated arthritis

In rare cases (less than 5%), patients with chronic HCV infection can develop an inflammatory arthritis that has been directly attributed to HCV infection.³³ The arthritis is a symmetric, nondeforming, nonerosive polyarthritis that involves small joints of the upper and lower extremities (metacarpophalangeal joints, proximal interphalangeal joints, ankles). Monoarthritis or oligoarthritis can be seen in 20% of cases. RF and cryoglobulin can be found in these patients, which makes the differential diagnosis from early RA or HCV-associated mixed cryoglobulinemia challenging.³³ The presence of anti-CCP antibodies and erosive changes on radiographs are helpful for excluding the diagnosis of RA. Analgesics, low-dose corticosteroids (less than 10 mg/day), and in severe cases disease-modifying antirheumatic drugs or anti-TNF agents can be used after appropriate evaluation and monitoring of hepatitis C.³³

Arthritis in hepatitis C virus–associated cryoglobulinemic vasculitis

Circulating cryoglobulins are a common laboratory finding in patients with chronic HCV infection (40% to 50% of cases), but less than 5% of patients develop the distinct syndrome of mixed cryoglobulinemia manifested by purpura, polyneuropathy, membranoproliferative glomerulonephritis, and other features.^{34,35} The clinical and laboratory manifestations of the syndrome are thought to be induced by monoclonal RF or immune complexes containing RF and polyclonal IgG, with or without associated HCV antigens, that are deposited in small-vessel walls in different tissues (skin, nerves, synovium, glomeruli).³⁴ The most common musculoskeletal complaints are intermittent nonspecific polyarthralgias involving the hands and knees, whereas less than 10% of patients develop inflammatory arthritis (nonerosive).

The diagnosis of arthritis in this setting is easier because patients have the typical clinical picture (purpura, skin ulcers, membranoproliferative glomerulonephritis, peripheral neuropathy), and laboratory findings (type II or III serum cryoglobulins, low C4 levels, RF, active urine sediment) of mixed cryoglobulinemia (Fig. 110.3).

The treatment of HCV-associated cryoglobulinemic vasculitis is guided by the severity and pattern of organ involvement. In patients with mild to severe disease, antiviral treatment (pegylated IFN- α plus ribavirin) with or without the addition of low-dose corticosteroids (prednisone at less than 10 mg/day) can lead to viral clearance and resolution of the mixed cryoglobulinemia syndrome.²⁶ In more severe cases, high-dose corticosteroids, cyclophosphamide, rituximab, and/or plasmapheresis followed by antiviral treatment have been used with very good success rates.^{36,37} In cases in which antiviral therapy has failed, is contraindicated, or is not tolerated, rituximab monotherapy has been used with success and without significant adverse effects.^{38,39}

Interferon- α -induced arthritis

IFN- α is an immunomodulatory cytokine with pleiotropic properties, and its use has been associated with a number of autoimmune manifestations, including autoimmune thyroiditis, arthritis, and lupuslike syndrome.³⁰ Arthritis is rare, and when it appears the decision to continue treatment depends on the severity of the IFN- α -induced arthritis as well as the likelihood of viral clearance with IFN- α therapy.

CHIKUNGUNYA AND OTHER ALPHAVIRUSES

Although alphavirus infections have long been associated with various forms of inflammatory arthritis, for Western rheumatologists these have not been infections of practical concern.⁴⁰⁻⁴² Table 110.1 lists the alphaviruses linked to arthritis, all of which are arboviruses.⁵

Over the past decade this pattern of limited spread has changed with the emergence of one alphavirus, namely chikungunya virus (CHIKV), which is no longer restricted to tropical developing countries and now poses a global public health problem. CHIKV, a single-stranded RNA virus, like other members of the genus, is a mosquito-borne virus that in the past has been responsible for significant epidemics in Asia and Africa.⁴¹ In 2006 an outbreak of CHIKV infection swept over several islands in the Indian Ocean and parts of India proper, and appeared most recently in Singapore. During this same time increasing numbers of cases were reported in travelers returning to Europe and the United States.⁴³ A major reason for this epidemiologic shift appears to be a single adaptive mutation enhancing CHIKV's ability to be carried by *Aedes albopictus*, a mosquito linked to urbanization and international transport.⁴⁴ Evidence of this threat is now documented by way of an outbreak of CHIKV in northwestern Italy, where more than 200 cases were described and traced to an infected traveler returning home with subsequent spread of the virus by *A. albopictus*.⁴¹

Clinical manifestations

Nearly all patients infected with CHIKV develop an inflammatory polyarthritis that, although generally short-lived, is clinically severe and may

TABLE 110.1

Alphavirus-related arthritis and geographic distribution

Alphavirus distribution	Geographic	Clinical manifestations	Comments
Ross River	Australia Oceania	Polyarthritis Fever Rash	Reported in travelers and visiting U.S. military personnel
Sindbis	Russia Finland Sweden	Arthritis Rash	Transmitted by mosquitoes from birds to humans
Mayaro	South America	Arthritis Fever	
O'nyong-nyong	Africa	Polyarthritis Fever Rash	Similar clinical picture to chikungunya virus
Igbo-ora	Central Africa	Arthralgias Fever Myalgias	
Chikungunya	Southeast Asia Africa	Polyarthritis Fever	Reported in travelers from endemic areas (e.g., Northern Italy, France)

Fig. 110.4 Chronic arthritis involving wrist and metacarpophalangeal and interphalangeal joints in a patient with chikungunya virus infection. (From Khasnis AA, Schoen RT, Calabrese LH. Emerging viral infections in rheumatic diseases. *Semin Arthritis Rheum* 2011;41:236-46).

BOX 110.3 CLINICAL AND LABORATORY FINDINGS OF CHIKUNGUNYA VIRUS INFECTION

A. Early phase (0-10 days)

Clinical

- Fever
- Symmetric polyarthritis (wrists, hands, ankles, toes)
- Rash
- Conjunctivitis

Laboratory

- Cytopenias (leukopenia, thrombocytopenia)
- Transaminasemia (aspartate aminotransferase, alanine aminotransferase)
- Detection of virus (virus isolation methods) or viral RNA (reverse transcriptase-polymerase chain reaction)

B. Late phase (>10 days)

Clinical

- Arthritis/tenosynovitis of hand joints (lasting up to 6 months)

Laboratory

- Detection of specific immunoglobulin M or immunoglobulin G antibodies (fourfold increase in paired samples)

mimic more serious and persistent forms of noninfectious arthritis. The disease has been reported to run through two consecutive phases (Box 110.3).⁴¹⁻⁴³ During the early phase (less than 10 days), manifestations include fever, transient rash (macular, papular, or generalized erythematous, located on the trunk), conjunctivitis, myalgias, and symmetric polyarthralgias and/or polyarthritis involving mainly the wrists, hands, ankles, and toes.^{40,41,43} Edema of the face and periarticular tissues is common in these patients. Axial pain is also common, affecting almost half of patients. During this phase, elevation of liver enzymes (AST, ALT, γ -glutamyltransferase) and muscle enzymes (creatinine phosphokinase, lactate dehydrogenase) have been documented in 50% of patients, often accompanied by cytopenias (thrombocytopenia, leukopenia). In some cases, petechial hemorrhages are also

noted. During the second stage of the disease (longer than 10 days), most patients have persistent joint pain in the form of tenosynovitis involving wrists and fingers and/or proximal finger joint arthritis. At this stage fever and rash have generally abated. Almost half of patients continue to have articular symptoms 6 months after the onset of disease, but laboratory results are normal during this phase. Rarely, the disease can follow a chronic course reminiscent of RA (Fig. 110.4).⁴⁵ Only symptomatic treatment with analgesics and nonsteroidal antiinflammatory drugs (NSAIDs) is given throughout the entire course of the disease, because no specific therapy is available. In certain cases, corticosteroids or methotrexate has been administered.^{40,45}

The diagnosis of CHIKV infection is based on clinical features (fever and arthralgias/arthritis), epidemiologic factors (residence in or return from an endemic area within 15 days of the onset of symptoms), and laboratory findings (virus isolation, detection of viral RNA, detection of specific IgM antibodies, fourfold increase in IgG titers).⁴¹ During the first week of febrile illness, virus isolation or detection of CHIKV RNA by reverse transcriptase-polymerase chain reaction assay is used, but later on the detection of antibody response (IgM antibodies) by indirect immunofluorescence or ELISA is necessary for diagnosis.⁴¹

HUMAN T-CELL LYMPHOTROPIC VIRUS TYPE I

HTLV-I infection, which is endemic in certain geographic areas such as southern Japan and the Caribbean, has been associated with an inflammatory arthropathy resembling RA.⁴⁶ The virus, a human retrovirus, is transmitted perinatally, sexually, and through contaminated blood transfusions. HTLV-I-associated arthropathy commonly affects elderly women and takes the form of a seropositive (RF+), symmetric, inflammatory arthritis. Radiographs of the affected joints usually reveal mild erosive changes. NSAIDs, DMARDs, and low-dose prednisolone have been used for its treatment.⁴⁶

OTHER VIRUSES

Rarely, other viruses have been implicated as causes of acute self-limited arthritis, including rubella virus,⁴⁷ Epstein-Barr virus,⁴⁸ and coxsackievirus.⁴⁹

Acute rheumatic fever

■ PEDRO MING AZEVEDO, SR. ■ ROSA MARIA RODRIGUES PEREIRA

- Acute rheumatic fever (ARF) is a systemic autoimmune disease triggered by cross-reactive immune responses between group A β -hemolytic streptococci (GAS) and host tissue epitopes.
- There is a 2- to 3-week latency period between the inciting GAS infection and ARF symptoms with the exception of chorea, for which the latency period is typically 4 to 8 weeks.
- ARF is most common among 5- to 15-year-old individuals, with a declining incidence in adults. This condition is rare in children younger than age 3.
- The acute form of the illness is characterized by all or a subset of the following symptoms: fever, arthritis, carditis, Sydenham chorea, erythema marginatum, and subcutaneous nodules.
- Chronic rheumatic heart disease is the primary cause of death in rheumatic fever and may be largely prevented by adequate antibiotic prophylaxis.

INTRODUCTION

The composer Wolfgang Amadeus Mozart (1756-1791) was tormented by frequent attacks of arthritis and appears to have been ultimately killed by heart failure (and renal dysfunction). The artist Andy Warhol (1928-1987) and the German poet Bertolt Brecht (1898-1956) both had St. Vitus' dance and died of heart failure. Rheumatic fever (RF) was once so common throughout Europe, the United States, and the rest of the world that the medical specialty of rheumatology owes its name to the disease referred to as *Rhumatism* by the 16th-century French Hellenistic doctor Guillaume de Baillou. The incidence of acute rheumatic fever (ARF) declined dramatically in the developed world throughout the 20th century, being restricted primarily to sporadic outbreaks. However, the disease remains a major medical and social problem in the developing world and so-called hotspots, where it still causes approximately 230,000 deaths annually.¹

EPIDEMIOLOGY

Denmark has the best historical records regarding the incidence of ARF, and this nation can be used as an example of what occurred in what is now referred to as the developed world. In 1862, this country recorded 250 cases per 100,000 inhabitants. However, in 1962, the incidence had dropped to 100 per 100,000. Between 1860 and 1945, when antibiotics became available, the disease incidence decreased by approximately 75%. By 1980, the incidence of ARF was approximately what it is currently, which is 0.3 per 100,000 inhabitants.² The reasons behind this dramatic decline in incidence before the use of antibiotics are incompletely understood but include improvements in living conditions and possibly changes in the infecting bacteria.

In the mid-1980s, ARF outbreaks were observed in Utah, Pennsylvania, Ohio, and military bases in San Diego and Missouri in the United States. The annual incidence at that time was as low as 0.23 to 1.88 per 100,000 among children and adolescents but increased approximately 10-fold in specific epidemic areas. The affected children in the Utah outbreak were primarily from upper-middle-class families who had full access to medical facilities, which highlights the role of factors other than poverty and overcrowding in the pathogenesis of this disease.³

Presently, the incidence of ARF in most developed countries remains below 5 per 100,000 inhabitants (Fig. 111.1). Australia and New Zealand are exceptions due to a high incidence of ARF in communities of individuals of Aboriginal and Polynesian descent. Such individuals do not have the same standard of living as those of European ancestry. Higher incidences of ARF are observed in the Aboriginal population of Australia, which exhibits annual rates above 300 per 100,000 inhabitants.⁴ The developing world has also witnessed a clear decline in the incidence of ARF, but the disease is still endemic in South America, Africa, and Asia, and in the less affluent communities of Australasia and the Pacific islands. Based on the few data that are available, the annual global incidence of ARF has been estimated to be approximately 471,000 cases, leading to a worldwide prevalence of rheumatic heart disease (RHD) of at least 15.6 million cases, with 282,000 new cases and 233,000 deaths due to RHD each year. Given that the progression of carditis is silent in most cases and that arthritis can be mild and easily controlled by regular use of antiinflammatory drugs, these numbers may be underestimates. In addition, fewer data are available from the areas in which the disease is more prevalent.¹

Relationship between group A streptococci and rheumatic fever

Consistent data strongly support a relationship between pharyngitis caused by group A β -hemolytic streptococci (GAS) and ARF⁵: (1) streptococcal sore throats or scarlet fever epidemics precede outbreaks of RF; (2) adequate treatment of streptococcal pharyngitis markedly decreases the incidence of subsequent RF; (3) secondary antimicrobial prophylaxis prevents the recurrence of ARF; and (4) antistreptococcal antibody titers are high in most patients with ARF, even if the patients do not recall preceding pharyngitis.

The laboratory and epidemiologic data that have been gathered over more than 60 years suggest that, in contrast to nephritis, RF is associated with pharyngeal but not skin infections. Moreover, GAS strains have been characterized as either "rheumatogenic" or "nephritogenic" based on their phenotypic and genotypic properties. ARF almost never occurs following outbreaks of impetigo. Although impetigo strains do colonize the pharynx, they do not appear to elicit a strong immunogenic response to the bacterial M protein. The pharynx is largely supplied with lymphoid tissue, a fact that is most likely important with respect to the initiation of the anomalous cross-reactive immune response. Nevertheless, the epidemiology of ARF in the Aboriginal populations of central and northern Australia runs counter to this view. Although this population has some of the highest reported rates of ARF and RHD, GAS throat carriage rates are low and symptomatic GAS pharyngitis is rare.⁴ In these high-risk populations pyoderma is the major manifestation of GAS infection, typical rheumatogenic strains do not occur,⁴ and a distinction cannot easily be made between the strains that cause ARF and those that cause glomerulonephritis based on genotype and the site of recovery. A possible causal link between GAS skin infection and RF in the tropics has been suggested and has been the subject of investigation in Australia⁶; however, the question of whether such a correlation exists remains open. In endemic settings, there is an increased genetic transfer of virulence factors between organisms, an effect that blurs the classic genotypic and phenotypic traits of the strains.⁴ Group C and G streptococci are more commonly observed in the throats of Aboriginal children and have been demonstrated to exchange key virulence determinants with GAS. It has been proposed that these strains may be involved in the pathogenesis of RF in such communities.⁶ An alternative explanation is that certain ethnic groups are predisposed to RF so that even the low observed pharyngeal GAS carriage rates are sufficient to cause higher rates of ARF and RHD.

Streptococcal factors

Streptococcus pyogenes, or GAS, is an anaerobic, facultative, gram-positive coccus that grows in chains and causes numerous infections in humans. Phenotypic and genotypic characteristics of the bacteria are determinants of its virulence and immunogenicity. The surface layer of the bacterial cell wall contains the M protein, a major virulence factor. It exhibits a great deal of variation in its N-terminal molecular structure, which allows GAS to be further differentiated into more than 130 M-serotypes. The abundant production of M protein may confer a mucoid appearance to colonies in blood-agar plates. The M protein binds to the Fc portion of immunoglobulin G and immunoglobulin A molecules, creating a human immunoglobulin shield with the Fab portion facing outward that prevents phagocytosis and immune recognition. Within the M protein lies a domain that binds to one of the complement regulatory proteins (factor H), inhibiting antibody binding and complement-derived opsonin deposition. The M protein has a helical and coiled structure that has structural homology with cardiac cytoskeletal tropomyosin and myosin and many other coiled structures, including vimentin, keratin, DNA, and lamin. T-cell clones from the heart valves of patients with RHD can be reactive to the epitopes of type 5 M protein.⁷ Cross-reactivity between the endothelium and sarcolemma antigens with M-protein structures have also been described.⁷ In the 1960s, 3 of 21 patients enrolled in an M-protein vaccine early trial developed ARF, which further indicates the pathophysiologic role of this structure.⁸ Nontypeable strains of GAS may express small quantities of M protein, express an entirely novel M protein that is not recognized by the current typing techniques, or completely lack M proteins. New M-types are frequently described, which poses a great challenge to bacteriologists. Several different M-serotypes and nontypeable GAS strains, both mucoid and nonmucoid, have been associated with RF. Moreover, different M serotypes have been linked to RF in different populations. Because GAS strains are able to transfer genetic material horizontally, it is believed that any GAS can potentially acquire the ability to cause RF. Although GAS organisms have many structures that may cross-react with joints, the heart, the skin, the kidneys, and the brain, the role of each specific antigen in RF pathogenesis remains unclear.

The decline of RF in the 20th century could possibly be linked to alterations in *Streptococcus*. Some experts believe that there has been a decline in the incidence of streptococcal infections, but there are no data that

document this hypothesis. Scarlet fever has become a much milder disease than in previous decades, and its incidence appears to have declined. The incidence of poststreptococcal acute glomerulonephritis also has declined, although not as markedly as has the incidence of RF.⁹ Changes in bacterial virulence were proposed to be a possible mechanism for this observed decline in incidence. The M protein is considered to be the major streptococcus virulence factor, but there are no data indicating that the percentage of non-M-typeable strains (i.e., strains lacking M protein) are increasing in prevalence.⁹

Environmental factors

RF is a disease of poverty. The influence of socioeconomic status on its prevalence is supported by the near disappearance of ARF in industrialized countries since the mid-20th century, which began before the introduction of antibiotics. In a study in the Congo, the prevalence of RHD, based on clinical examination, was 22.2 per 1000 among children who lived in slums but only 4 per 1000 among children who attended schools.¹⁰ The exact poverty-related factors that lead to RF susceptibility are incompletely understood. Crowding is associated with lower social indices and is a facilitating factor for the spread of streptococcal infection. In early U.S. military studies, the acquisition of pharyngeal GAS was inversely proportional to the distance between barrack beds.¹¹ Nevertheless, not all authors have been able to demonstrate an association between crowding and ARF. Maternal unemployment and treatment noncompliance have also been associated with both low socioeconomic status and ARF.¹²

Host factors

During the U.S. military base outbreak in the 1950s, only approximately 3% of individuals infected with the rheumatogenic *Streptococcus* strains developed ARF. During the Utah epidemic in the 1980s, the majority of affected children, as noted earlier, were from upper-middle-class homes with access to medical facilities, which suggests that individual factors are important in the pathogenesis of this disease. Additionally, only a very small percentage of patients develop all of the associated symptoms,¹³ and only one to two thirds develop chronic rheumatic heart disease (CRHD).¹⁴ Individual factors are determinants of the disease pattern but are poorly understood. Familiar

aggregation, the similarity of disease patterns in siblings and identical twins, and HLA correlation studies provide evidence for a genetic influence on RF susceptibility and manifestation; however, this influence does not appear to be single-gene/mendelian in nature.¹⁴ The pooled probandwise concordance risk for acute rheumatic fever was 44% in monozygotic twins and 12% in dizygotic twins, and the association between zygosity and concordance was strong (OR 6.39; 95% confidence interval, 3.39 to 12.06; $P < 0.001$), with no significant study heterogeneity ($P = 0.768$). The estimated heritability across all the studies was 60% and RF was considered an autoimmune disorder with a high heritability.^{14a}

Given the evidence for a genetic component of RF susceptibility, several genes have been examined for a possible role, the majority of which are in some manner involved in the regulation of the immune system. These proposed genetic factors include genes that encode HLA antigens and B-cell alloantigens, as well as polymorphisms within immune system-related genes.

HLA class II antigens

Different HLA class II antigen associations have been observed in several populations, chiefly those encoded by the DR and DQ genes. The HLA class II gene most consistently associated with RF/RHD was HLA-DR7, observed in Brazilian, Egyptian, Latvian, and Turkish patients. The combination of HLA-DR7 with certain HLA-DQB or HLA-DQA alleles was associated with multiple valvular lesions in patients with RHD in Egypt and Latvia.⁷ The HLA class II genes encode cell-surface proteins that present outer antigens to the T-cell receptor (TCR). It is the HLA-antigen complex that is recognized, not the antigen alone; it is therefore plausible that the HLA type has a direct influence on RF pathophysiology. Accordingly, the M5 immunodominant epitope was preferentially presented to T cells in the context of specific HLA class II molecules (DR7 and DR53).⁷ Because different strains of GAS with different immunogenic properties cause RF in different countries, it is unsurprising that diverse HLA class II associations have been reported. The HLA gene complex may also be in linkage disequilibrium with the actual RF susceptibility genes and may thus serve only as a marker.

B-cell alloantigen

In 1979, it was observed that the serum from a multiparous woman reacted with RF patients' blood with a higher frequency than with control serum. The alloantigen was demonstrated to be at the B cells' surface and was not associated with any specific major histocompatibility complex. A monoclonal antibody (D8/17) was subsequently produced by immunizing mice with B cells from patients with RF. The B-cell antigen was highly expressed on 100% of B cells from RF patients in several ethnic groups but in only 10% of samples from controls.¹ The D8/17 target antigen shares antigenic determinants with heart and streptococcal membrane cross-reactive antigens. This monoclonal antibody also reacted with cells of the Aschoff bodies, which express HLA-DR molecules. This result suggests that these cells act as antigen-presenting cells and elicit a delayed immune reaction.¹⁵ However, the D8/17 marker was absent in one third of North Indian patients. Using the same technique, a novel monoclonal antibody (PGI/MNII) was developed for this population and also exhibited a high sensitivity (identifying 86% of patients with RF and 94% of patients with RHD).¹ These results suggest that different epitopes are presented to the adaptive immune system in the two populations, perhaps in the context of different class II HLA molecules.

Gene polymorphisms

The innate immune response provides a direct defense against infection, recruits immune cells to the site of infection, and activates the adaptive immune system via antigen presentation, the production of cytokines, and initiation of the complement cascade. Variations within the genes involved in the innate immune response could influence an individual's predisposition to GAS infection, ARF, or its sequelae. It follows that polymorphisms in the genes that code for proteins involved in the innate immune response have been associated with RF and/or its manifestations. These genes include mannose-binding lectin, Toll-like receptor 2, and ficolin-2, which is a receptor for the Fc fragments of immunoglobulin G (FcγRIIA) and a macrophage migration inhibitory factor.

The agent primarily responsible for the maintenance and expansion of the inflammation that leads to the tissue damage observed in RHD is the adaptive immune system. To date, the genes or genomic regions that have been associated with RF and/or its manifestations include interleukin-1 (IL-1) receptor antagonist, tumor necrosis factor- α (TNF- α), the IL-10 gene promoter, transforming growth factor- β , and cytotoxic T-lymphocyte antigen 4.⁷

HUMORAL IMMUNE RESPONSE

Several antibodies that are capable of cross-recognizing human and streptococcal molecules have been described.¹⁴ Antibodies against the streptococcal wall component GlcNAc display cross-reactivity against laminin, which is present in the extracellular matrix of both the myocardium and heart valves. Cardiac myosin and vimentin are other chief target antigens in RF. Cunningham and colleagues¹⁶ identified a five-amino-acid residue epitope of the streptococcal N-terminal M5 and M6 proteins that cross-reacts with cardiac myosin. Sydenham chorea is believed to be mediated by antibodies that bind to neurons. Antibodies against streptococcal GlcNAc cross-react with lysoganglioside GM1 from neurons, producing an effective signal transduction pathway that prompts dopamine release from neurons.¹⁴ It is clear that not all autoantibodies mediate disease, and a subset of these may even have a protective role in the clearing of circulating antigens. Nevertheless, Cunningham's group demonstrated that RF patients' antimyosin and antilaminin antibodies upregulate the expression of the vascular adhesion molecule VCAM-1 after binding to the endothelial surface and promote immune cell infiltration, inflammation, and valve scarring.¹⁴

CELLULAR IMMUNE RESPONSE

The heart lesions that are observed in patients with RHD are primarily mediated by CD4+ lymphocytes.¹⁴ The peripheral and intracardiac T cells of patients with RF are able to cross-recognize several self and streptococcus epitopes, specifically cardiac myosin, laminin, and tropomyosin as well as certain bacterial M5 protein.¹⁴ These M5 epitopes preferentially recognize peripheral T lymphocytes from patients with RHD over those from healthy individuals.⁷ There is evidence that a cross-reactive T-cell population migrates from the periphery to the heart, where it expands in an oligoclonal manner.⁷ Several intralesional T-cell clones present the same amino acid sequences in the CDR3 region of the TCR, which indicates degeneracy in antigen recognition.⁷ Together, these data support the idea that antigen-specific peripheral T-cell populations migrate to the heart tissue, expand locally, and become capable, via an epitope-spreading mechanism, of recognizing novel self-antigens that are distinct from the initial pathogen antigen.⁷

CYTOKINES IN RHEUMATIC FEVER

Transient and mild carditis, like Sydenham chorea and arthritis, are believed to be mediated primarily by humoral immunity (i.e., the helper T cell 2 [Th2]-type immune response),¹⁴ whereas severe and persistent carditis is mediated by cellular immunity (i.e., the Th1-type immune response).¹⁴ Antigen-activated CD4+ T cells become polarized toward a Th1 or Th2 phenotype based on the cytokines they secrete. In the classic 1951 Bland and Jones series of 1000 patients, those with chorea had a better prognosis (less severe carditis),¹⁷ which suggests that a trend toward a Th2-type immune response somewhat diminishes the likelihood of Th1-mediated involvement. The same finding was observed in other series but is not consistently reported.⁷

Several results suggest that RF patients exhibit a more severe and longer-lasting immune reaction than unaffected individuals. Compared with the lymphocytes of patients with acute poststreptococcal glomerulonephritis, the lymphocytes of patients with ARF exhibit exacerbated *in-vitro* cellular reactivity that peaks after 1 to 6 months and lasts for a minimum of 2 years after onset.¹⁴ Stimulated peripheral blood mononuclear cells from patients with ARF produce higher levels of IL-1, IL-2, and IL-2 receptors (CD25) than peripheral blood mononuclear cells from normal control subjects or patients with streptococcal pharyngitis or CRHD. The observed IL-2 overproduction persisted following 48 weeks of throat infection. IL-1 stimulates IL-2 and CD25 production; thus IL-1 was considered to be primarily responsible for the persistent inflammatory process.¹⁴ Another study also observed higher IL-1 and IL-2 concentrations in patients with ARF than in patients with streptococcal pharyngitis, patients with CRHD, and healthy control subjects. In this study, the production of IL-2 in patients with ARF and CRHD was correlated with altered proportions of CD4+ (Th) and CD25+ cells in the peripheral blood.¹⁸

In the heart tissue (i.e., the myocardium and heart valves) of patients with RHD, large numbers of mononuclear cells secrete inflammatory mediators (TNF- α , interferon- γ , IL-1, and IL-2) and regulatory mediators (IL-10, IL-4, and IL-1 receptor antagonist [IL-1Ra]). The analysis of the cytokine profile of these cells suggested that Th1-type cytokines are involved in the mediation of chronicity and that the regression of myocardial inflammation

Fig. 111.2 Pathophysiologic model for rheumatic fever. GAS, group A streptococci; IL, interleukin; IL-1Ra, interleukin-1 receptor antagonist; Th1, Th2, type 1 and 2 helper T cells; TNF- α , tumor necrosis factor- α ; VCAM-1, vascular cell adhesion molecule 1. (Modified with permission from Azevedo PM, Pereira RR, Guilherme L. Understanding rheumatic fever. *Rheumatol Int* 2012;32[5]:1113-20.)

depends on the regulatory function of IL-10 and, most importantly, IL-4. Only small numbers of IL-4-producing cells were observed in the valves of patients with CRHD, and the lack of this cytokine was implicated in the perpetuation of valvular inflammation.⁷ Another lineage of CD4+ T cells that produce IL-17 and IL-23 has been recently described in the myocardium and valvular infiltrating cells. This result indicates that Th17 cells are important effectors of the inflammatory process in RHD heart lesions.

A protective association was suggested between the IL-1Ra genotype that is classically associated with a milder immune response and the development of severe carditis in 84 Brazilian patients with RF.¹⁴ IL-1Ra production acts as a major stop signal for inflammation in the Th1 immune response and could diminish the possibility of chronification and epitope spreading. Ongoing inflammation in children that progressed to RHD was documented through the persistence of elevated levels of both C-reactive protein (CRP)¹⁹ and proinflammatory cytokines.²⁰

In summary, molecular mimicry and autoimmunity are not sufficient to explain RF. RF patients exhibit a more severe and longer-lasting cytokine-mediated immune reaction than unaffected individuals. Genetic variation, particularly in the genes involved in immune system regulation, help explain the prevalence of RF-related dyscrasias (Fig. 111.2).

PATHOLOGY

Cardiac involvement in RF is loosely classified as acute and chronic. The pericardium, myocardium, and endocardium can be affected (i.e., pancarditis) in RF.

Myocarditis

In the acute phase, a dilation of the chambers may be observed; the autopsy may reveal a pale, flabby, and edematous myocardium. The initial histologic alterations consist of nonspecific myocarditis with edema of the muscle fibers and focal collections of inflammatory cells in the interstitium. Subsequently, a more specific granulomatous myocarditis may occur, occasionally with the presence of distinctive Aschoff nodules. Fully developed Aschoff nodules are composed of a central area of fibrinoid change that is surrounded by lymphocytic infiltration (occasionally of plasma cells), specialized histiocytes that are referred to as *Aschoff giant (multinucleated) cells*, and *Anickov cells* (also known as *caterpillar cells* due to the appearance of their chromatin). Stollerman^{20a} defined three phases in the progression of Aschoff nodules: (1) the early stage, which is characterized by central fibrinoid necrosis, edema, and an infiltrate of lymphocytes and plasma cells (nonspecific stage

or exudative-degenerative phase); (2) the specific granulomatous stage, which is characterized by the accumulation of characteristic Aschoff giant cells and Anickov cells; (3) the late stage, which is characterized by the diminution of the cellular infiltrate and its replacement by scar tissue.

Significant inflammation is relatively uncommon in CRHD. Histologically, neovascularization, fibrosis, and relatively mild calcification are typical. Histiolympocytic reactivity, lymphocytic infiltrate, and Aschoff nodules are rarely observed.²¹

Endocarditis

In its early stages, endocarditis is associated with edema of the valves and possibly vegetations along the free borders of the cusps. These minute vegetations are platelet-rich microthrombi (marantic vegetations), which do not become dislodged and hence do not produce emboli. During healing, vascularization and fibrosis occur. In the majority of cases, fibrosis does not affect the function of the valve. In other cases, the scarring is progressive over years and may affect the subendocardial tissue as well as the annulus, cusp, and chordae tendineae. These changes can cause a contraction of the cuspid or thickening and stiffening of the cusp, resulting in valvular incompetence or the fusion of the commissures and leading to stenosis. Why a subset of patients exhibit progressive scarring whereas others do not is incompletely understood. Recurrent *Streptococcus* infection is a clear cause, but an unfavorable progression is occasionally observed in patients with only one documented ARF episode. The intensity of the inflammatory process in each attack is most likely a factor. A jet of blood that squirts through the incompetent mitral valve can in rare cases produce a patch of endocardial thickening where the jet hits the atrial wall (jet lesion); this indicates that constant blood turbulence can cause endocardial fibrosis, which is one of the mechanisms of scarring progression. This scarring may be mediated by the release of growth factors from platelets and other components of small mural thrombi. Tissue from valve and papillary muscles, which are collected during valve replacement procedures in CRHD patients, occasionally exhibits some mononuclear or lymphocytic infiltrates, and Aschoff nodules are rarely observed, even in patients whose disease was considered to be in remission based on laboratory and clinical findings.^{22,23} These results indicate that subclinical recurrent or persistent inflammation plays a role in the progression of valve destruction.

Pericarditis

Pericarditis affects both the fibrous and serous pericardium layers, which are potentially thickened and covered by a fibrin-rich exudate. A

serosanguineous pericardial effusion is occasionally observed. Pericarditis resolves completely with fibrosis and adhesions, but constriction does not occur.

Arthritis

In RF-related arthritis, the synovial fluid is sterile and shows inflammatory features. There may be a reduction in the levels of complement components C1q, C3, and C4, which suggests their consumption by immune complexes.

Chorea

Neuropathologic autopsy studies of patients with Sydenham chorea have reported neuronal degeneration and vascular alterations in the cerebral cortex, basal nuclei, and cerebellum. Antibodies against antigens in the cerebral cortex and caudate and subthalamic nuclei have been observed via immunofluorescence. Imaging case series have revealed acute changes in the caudate nucleus and subcortical white matter; some of these changes were persistent after a year.²⁴

Pathophysiologic model of disease

The information presented earlier implies a model of RF pathophysiology in which throat infection by a GAS strain that bears epitopes similar to human antigens (molecular mimicry) is initially fought by the innate immune system (see Fig. 111.2). The locally activated adaptive immune response then overproduces proinflammatory cytokines and antibodies, a subset of which are capable of cross-reacting with human and bacterial epitopes. The cytokines act systemically, activating and expanding multiple lymphocytes clones. At the joints, these antibodies precipitate in the form of an immune complex and activate the complement system, inducing arthritis. Certain antibodies may recognize basal ganglia neurons and induce dopamine secretion, which leads to Sydenham chorea and most likely obsessive-compulsive disorder in certain patients. It is possible that a trend toward Th2-type systemic immune response implies a less exacerbated Th1 response, conferring some cardioprotective effects. Certain autoantibodies against heart structures, primarily those derived from myosin, laminin, and tropomyosin, promote the expression of adhesion molecules such as VCAM-1, which initially induces the recruitment of monocytes and macrophages. These mononuclear cells produce a large number of cytokines, which act locally with proinflammatory and antiinflammatory properties. The balance between these cytokines determines the magnitude of the attraction of peripheral lymphocytes to the heart and the severity of the local inflammation. Degeneracy in antigen recognition and epitope spreading may occur, leading to persistent and intense inflammation and heart damage. If antiinflammatory cytokines have a greater effect, the inflammation ends and little, if any, heart damage occurs. In this model, possible points at which the host genetic background may have an influence are the exacerbated initial immune response, HLA/TCR epitope presentation (and thus molecular mimicry and adaptive system activation), systemic Th1/Th2

balance, and local cytokine balance, which determines whether inflammation continues or ends.¹⁴

CLINICAL MANIFESTATIONS

ARF manifestations vary greatly among individuals and among patients of different ages. Differences are also observed in the findings of prospective and retrospective studies (Table 111.1).

RF is rare before the third year of life and is infrequent in individuals who are older than 15 years of age; the majority of cases occur in individuals between the ages of 4 and 9 years. Small children tend to exhibit fever and carditis more frequently, whereas arthritis is more common in adults. If fever is present, it may be high or low. Arthritis is the most common of the major manifestations, followed by carditis and chorea. The symptoms generally begin 2 to 3 weeks after the GAS infection (average, 18.6 days; 4 to 6 weeks in cases of chorea). However, approximately one third of patients cannot remember having an airway infection. The period between the infection and the onset of ARF is free of clinical and laboratory evidence of inflammation.

Arthritis

Arthritis is generally the earliest major symptom of ARF, although carditis occasionally may occur first. Arthritis is more severe and more common in young adults (nearly 100% of cases) than in teenagers (82%) and children (66%). The traditional term *migratory* does not necessarily indicate that the inflammation disappears in one joint and appears in another. The affected sites generally overlap in time, and the progression may also be additive. Monoarticular involvement was described in only 17% to 25% of the patients in older series. However, since nonsteroidal antiinflammatory drugs (NSAIDs) alter the natural course of the arthritis and potentially abort the migratory pattern, monoarthritis is now more common. Untreated patients typically exhibit 6 to 16 involved joints. Large joints such as the knees, ankles, elbows, and wrists are the most frequently involved, and the lower limbs are normally the first to be affected. The hip, shoulder, and phalangeal joints are less frequently involved. The inflammation lasts for a few days to a week for each articulation²⁵; however, the entire articular picture is intense for approximately 1 week and may linger for another 1 to 2 weeks. If joint swelling persists after 4 weeks, it is necessary to reconsider the diagnosis. Joint pain may be sufficiently severe to limit movement significantly and is generally disproportional to the objective signs of inflammation. Radiographic findings are normal, except for occasional effusion. No erosion is observed.

Jaccoud arthropathy, or chronic post-RF arthropathy, is a rare manifestation of RF that may occur following repeated attacks of arthritis. This condition results from recurrent inflammation of the fibrous articular capsule that leads to ulnar deviation of the fingers, particularly the fourth and fifth fingers; flexion of the metacarpophalangeal joints; and hyperextension of the proximal interphalangeal joints. The deformities are generally correctible but may become fixed in later stages. A similar form of arthropathy is observed in patients with systemic lupus erythematosus.

■ TABLE 111.1 Percentages of patients meeting major and minor criteria by WHO region and for all reported studies

WHO region	Males	Recurrences	Major criteria					Minor criteria

Carditis

Acute rheumatic carditis

Heart murmurs, cardiomegaly, and congestive heart failure are all signs and symptoms of acute rheumatic carditis, although a subset of patients are asymptomatic. Pleuritic chest discomfort or pain and pericardial friction rub are indicators of pericarditis, which is present in approximately 10% of patients. The pericardial effusion may be large, but cardiac tamponade is rare. Valvular inflammation and deformity cause new or changing organic murmurs, most commonly mitral regurgitation. Aortic regurgitation and systolic ejection murmurs are occasionally observed. The classical Carey Coombs mid-diastolic murmur is rare and is caused by a rapid overflow of the mitral valve.

Mitral regurgitation is the most common early valvular finding and may be accompanied by aortic regurgitation. Isolated aortic regurgitation is less frequent. Mitral regurgitation can be caused by a prolapsed mitral valve, which chiefly involves the anterior leaflet, with minimal leaflet redundancy. This presentation is in contrast with that in myxomatous disease, which more commonly involves the posterior leaflet and is associated with prominent leaflet redundancy. Valve prolapse is due to annular dilation and chordal elongation. Aortic or mitral stenosis is atypical at presentation. Congestive heart failure is the most life-threatening feature of ARF and can develop if severe valvular damage occurs in addition to cardiac dysfunction. Congestive heart failure occurs in 5% to 10% of initial ARF episodes and is more frequent during recurrences. This complication must be treated rapidly and aggressively with diuretics and antiinflammatory drugs. Myocarditis in the absence of valvulitis is unlikely to be rheumatic. Varying degrees of heart blockage can be observed on electrocardiography. Second- and third-degree blockage may require short-term use of a pacemaker if it is associated with congestive heart disease.

The incidence of carditis during the initial ARF attack varies from 40% to 91%, depending on the selection of patients and whether the diagnosis is made on a clinical basis or in combination with echocardiography (see Table 111.1).

Transition from acute to chronic heart disease

In the series reported by Bland and Jones,¹⁷ signs of rheumatic valvular disease had disappeared in 17% of the patients after 20 years. However, 44% of the patients who did not exhibit clinical carditis at presentation later developed overt signs of valvular heart disease. In total, 70% of the patients eventually developed CRHD. A more modern prospective study of 258 Brazilian children with ARF revealed that 72% of the patients developed chronic valvular disease based on echocardiographic findings, and 37% exhibited this condition based on a clinical assessment. Forty-one children (16%) eventually developed severe aortic and/or mitral disease. The risk factors for progression to severe chronic valvular disease were moderate or severe acute carditis, recurrences of ARF, and a low educational level of the mother.²⁶

Subclinical indolent carditis

Although clinically evident recurrences of ARF are associated with the development and severity of CRHD, this outcome is also possible in patients with a history of only one⁵ or no ARF attacks. Subclinical cases of carditis comprise a substantial portion, perhaps the majority, of CRHD cases.²⁷

Chronic rheumatic heart disease

CRHD is the single greatest cause of acquired valvular disease in the world and is responsible for approximately one in four cases of heart failure in endemic countries. In the majority of cases, the valvular disease occurs 10 to 20 years following the original ARF episode. Patients who are younger than age 30 generally have pure mitral regurgitation, whereas middle-aged adults develop mitral stenosis. Mixed mitral valve disease becomes more prevalent in patients who are older. Mitral valve involvement is nearly universal; the aortic valve is involved in approximately 20% to 30% of cases. The tricuspid valve is frequently affected, but this involvement is often subclinical until surgery is required. The pace of progression of mitral stenosis varies among geographical areas. In developed countries, the stenosis normally progresses slowly over 20 to 40 years until the onset of symptoms. In developing countries, mitral stenosis may progress rapidly, and symptoms are possible in patients who are younger than 5 years of age. There is normally a long period during which RHD remains asymptomatic and, if new ARF episodes do not come to the attention of a physician, frequently goes unnoticed. In a survey of 12,000 black schoolchildren in South Africa, 82.5% of the children found to be affected were previously undiagnosed.²⁸ Sixty percent of patients who are asymptomatic or minimally symptomatic

at the time of diagnosis will not experience any progression of the symptoms over 10 years, and survival is over 80% in such cases. Once limiting symptoms (New York Heart Association functional class III or IV) develop, survival without surgery is estimated to be between 0% and 15% over 10 years. Survival falls to less than 3 years in the presence of severe pulmonary hypertension.²⁵

Sydenham chorea

Sydenham chorea (also known as *St. Vitus dance* and *chorea minor*) is a neurologic condition characterized by abrupt, nonrhythmic, jerky, and purposeless movements; muscular weakness; and emotional disturbances. The movement abnormalities affect the hands, arms, shoulders, feet, legs, face, and trunk. These movements are frequently more striking on one side, are occasionally unilateral (hemichorea), and cease during sleep. Other symptoms include dysarthria, gait disturbance, the loss of fine and gross motor control, headache, slowed cognition, facial grimacing, and hypotonia. Moreover, there may be tongue fasciculations ("bag of worms") and "milkmaid's sign," which is a recurring grip characterized by alternate increases and decreases in handgrip tension, as if hand milking.²⁵ It may initially be possible for the patient to suppress these movements voluntarily, but they potentially intensify to the point of seriously impairing daily activities. Handwriting generally becomes clumsy and provides an opportune manner of following the patient's course. The latency period between the streptococcal infection and the development of chorea is generally 6 to 8 weeks but may extend to 8 months. In the series of 1000 patients described by Bland and Jones, 51.8% had chorea, and the condition was associated with less severe carditis and a better prognosis.^{17,25} More recently, chorea has been reported to occur in 20% to 30% of patients with ARF. Females are more often affected than males, and most of the patients are children. Sydenham chorea is relatively rare in adults and, in most cases, patients also had the condition during childhood. Approximately 50% of patients with acute Sydenham chorea recover spontaneously after 2 to 6 months, although symptoms can persist for up to 2 years. Chorea may be the only manifestation of ARF, but all patients should undergo echocardiography to exclude silent carditis. The emotional disturbances may precede the motor symptoms and are characterized by outbursts of inappropriate behavior, including crying, restlessness, and irritation. Psychological manifestations may be severe and, in rare cases, result in transient psychosis.

PANDAS

PANDAS is an acronym for pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections. It was observed that in the years following a chorea attack, a subset of patients exhibit behavioral disturbances, such as tics and obsessive-compulsive disorders (OCDs). This finding, together with the presence of antibodies against neurons in the sera of patients with Sydenham chorea, led to the hypothesis that a prior streptococcal infection may cause these behavioral alterations. A strong association between the D8/17 cell marker and OCD was described.^{29,30} Although it is largely accepted that a streptococcal infection can worsen OCD symptoms in a subset of patients, the PANDAS hypothesis is controversial, and the question remains open.

Erythema marginatum

Erythema marginatum, which is also referred to as *erythema annulare* because of its ringlike appearance, is an infrequent RF manifestation that affects the limbs and trunk but spares the face. It is an evanescent, pink (or faintly red), nonpruritic, and nontender rash that extends centrifugally while the center returns to normal—hence the term *marginatum*. The border is irregular, serpiginous, and sharp on the outside edge, whereas the border is diffuse on the inside edge. A hot shower may reveal discrete lesions that may appear, disappear, and reappear in a matter of hours. Erythema marginatum is strongly associated with carditis and may occur at any time in the course of RF, occasionally in the chronic heart disease phase.

Subcutaneous nodules

Subcutaneous nodules in RF resemble those in rheumatoid arthritis but are smaller and last for a shorter period of time. In both diseases, these nodules occur over bony surfaces or near tendons (e.g., the occiput, elbows, knees, ankles, Achilles tendons), with a predilection for the elbows; however, in RF these nodules are generally observed 3 to 4 cm distal to the olecranon. The nodules are firm, painless, and not anchored

to the adjacent surfaces; the overlying skin is not inflamed. The size of the nodules varies from a few millimeters to 2 cm, and the duration does not exceed 1 month. The number of nodules varies from one to a few dozen (with an average of four), and they tend to occur in crops with a symmetric distribution when abundant. Subcutaneous nodules were described in 8.8% of patients in the Bland and Jones series¹⁷ but in only 1.5% of patients in a more recent series of 786 patients.³¹ Nodules are more common in patients with a history of prolonged active carditis than those in the early stages of the disease, and the appearance of multiple crops of nodules may be related to the severity of the RHD.

INVESTIGATIONS

The evaluation of a patient with suspected ARF involves searching for evidence of streptococcal infection, documenting the presence or persistence of an inflammatory process, and diagnosing and following the course of carditis.

Throat cultures

By the time the symptoms of RF appear, approximately 75% of patients have negative throat culture results.²⁵ A positive throat culture finding may be due to convalescent carriage of the original rheumatogenic strain or a new infection.

Streptococcal antibody tests

The available antibody tests are directed against the extracellular products of streptococci and include the anti-streptolysin O (ASO), anti-DNAse B, antihyaluronidase, anti-NADase (anti-diphosphopyridine nucleotidase), and antistreptokinase tests. Antibody titers peak at approximately 4 to 5 weeks following the infection, which normally coincides with the second or third week of RF. The titers then decline relatively rapidly over the next several months and more slowly after 6 months. Asymptomatic pharyngeal streptococcus carriers generally exhibit titers just above the limits of detectability; a high titer therefore indicates a true infection. To confirm a recent infection, however, a significant increase in the titer should be documented in a sample that is collected when the diagnosis of ARF is first suspected and in another sample obtained 2 weeks later. Patients with documented ARF will exhibit raised titers of ASO, which is the most widely used test, in approximately 80% of cases. Approximately 90% of them will exhibit positive test results if two antigens are evaluated, and approximately 95% will exhibit positive results if three antigens are used.

Rapid streptococcus antigen test

The rapid streptococcus antigen test (RSAT) has a specificity of 95% or higher and a sensitivity that varies between 65% and 90%.³² A positive RSAT finding is useful in establishing the diagnosis of GAS pharyngitis, but a negative RSAT result does not exclude this diagnosis.

Acute-phase reactants

The erythrocyte sedimentation rate and CRP levels increase during an ARF attack, except in situations in which chorea or erythema marginatum are the only manifestations. Salicylates or antiinflammatory drugs may mask the results of these tests, which are particularly useful in monitoring rebounds of rheumatic inflammation when treatment is being discontinued. If the test results are normal a few weeks following the cessation of therapy, the ARF attack is likely over, unless chorea appears. Erythrocyte sedimentation rate may remain elevated for up to 2 months following an episode of inflammation, whereas CRP levels normalize within days.

Other laboratory tests

A mild normochromic normocytic anemia may be present during ARF, but red cell counts generally normalize following the cessation of inflammation. The D8/17 monoclonal antibody test (mentioned earlier) is helpful in differentiating ARF from other disorders but is not commercially available.

Chest radiography

An enlarged heart silhouette may be present on the chest radiograph secondary to myocardial dilatation and/or pericardial effusion.

Electrocardiography

Tachycardia and prolongation of the PR interval are features of myocarditis. In rare cases, third-degree heart block may be observed. Pericarditis can induce diffuse elevation of the ST segments. Electrocardiographic abnormalities are present in approximately 21% of patients, with 60% of these patients exhibiting some degree of heart block.

Echocardiography

Echocardiography is approximately 10-fold more sensitive than auscultation in identifying valvular involvement.²⁵ Echocardiography confirms the clinical diagnosis of valvular lesions and aids in the exclusion of nonrheumatic causes of valvular damage. This technique is therefore used extensively in clinical practice. Nevertheless, echocardiographic indicators were not included in the 2002-2003 World Health Organization (WHO) RF/RHD criteria. This decision was made primarily (1) to avoid hindering the diagnosis when echocardiography is unavailable and (2) because most cases of subclinical carditis exhibit a benign evolution.²⁵ The echocardiographic documentation of isolated mitral and/or aortic regurgitation is not diagnostic of rheumatic valvulitis. Physiologic valve regurgitation is a common finding in healthy individuals and may be present in viral myocarditis and other conditions. The World Heart Federation recently proposed criteria for the echocardiographic diagnosis of RHD.³³

Echocardiographic population screening efficiently identifies asymptomatic patients with RF, who can then be enrolled in secondary prevention programs. These screenings may therefore be justified and cost effective in high-prevalence areas.^{34,35}

DIAGNOSIS

No single clinical or laboratory finding is diagnostic of ARF except perhaps the presence of Sydenham chorea. Therefore a set of diagnostic criteria was developed in 1944 by Jones and colleagues.^{35a} These criteria were modified in 1956 and revised in 1965. In 1988, WHO developed a new set of criteria, which was updated in 1992 by the American Heart Association.³⁶ More recently, a WHO 2002-2003 Expert Consultation Report modified the previous diagnostic criteria²⁵; these updated criteria are provided in Table 111.2. Each change of the Jones criteria is made to improve specificity at the expense of sensitivity, largely in response to the falling incidence of ARF in the USA. As a result, the criteria may not be sensitive enough to pick up disease in high incidence populations. Important circumstances where ARF can be diagnosed without fulfilling the Jones criteria include chorea and carditis of insidious onset and slow progression as the only manifestations of ARF. RF should be diagnosed even in the absence of evidence of a preceding GAS infection in these patients, and as well in those with chronic valve lesions of RHD. Doppler echocardiographic examination should be performed if the facilities are available and are currently integrated in the RF guidelines of countries with high incidence as Australia and New Zealand.^{36a}

PRIMARY PREVENTION (PHARYNGITIS TREATMENT)

In 2009, the American Heart Association released a statement regarding the prevention of RF and the diagnosis and treatment of acute streptococcal pharyngitis.³⁷

Antibiotic treatment of streptococcal pharyngitis diminishes the duration and intensity of streptococcal antigen exposure and can prevent most cases of ARF.²⁵ Streptococcal pharyngitis should be treated with antibiotics, and penicillin is the drug of choice because it is bactericidal. This drug can be given as a single intramuscular injection of benzathine benzylpenicillin G (600,000 units in children who weigh less than 27 kg, and 1.2 million units in those who weigh over 27 kg) or as 10 days of oral penicillin V (phenoxymethylpenicillin 40 mg/kg per 24 hours, given in three equal doses, not to exceed 750 mg for those weighing <27 kg, and 500 mg two to three times daily in adolescents and adults).³⁷ Oral administration has the disadvantage of noncompliance. Patients who are allergic to penicillin should be given a 10-day course of oral erythromycin (erythromycin estolate 20 to 40 mg/kg/day in two to four divided doses, or erythromycin ethylsuccinate 40 mg/kg/day in two to four divided doses, with a maximum dosage of 1 g/day).³⁷

According to a 2009 Cochrane review, a 3- to 6-day course of oral antibiotics (azithromycin, clarithromycin, and cefuroxime) is similar to 10-day

TABLE 111.2
2002-2003 WHO criteria for the diagnoses of rheumatic fever and rheumatic heart disease

Diagnostic categories	Criteria
Primary episode of rheumatic fever ^a	Two major* or one major and two minor** manifestations, plus evidence of a preceding group A streptococcal infection***
Recurrent attack of rheumatic fever in a patient without established rheumatic heart disease ^b	Two major or one major and two minor manifestations, plus evidence of a preceding group A streptococcal infection
Recurrent attack of rheumatic fever in a patient with established rheumatic heart disease	Two minor manifestations, plus evidence of a preceding group A streptococcal infection ^c
Rheumatic chorea and insidious onset of rheumatic carditis ^b	Other major manifestations or evidence of group A streptococcal infection are not required
Chronic valve lesions of rheumatic heart disease (patients presenting for the first time with pure mitral stenosis or mixed mitral valve disease and/or aortic valve disease) ^d	No other criteria required for diagnosis of rheumatic heart disease

*Major manifestations: carditis, polyarthritis, chorea, erythema marginatum, and subcutaneous nodules.

**Minor manifestations: clinical findings—fever, polyarthralgia; laboratory findings—elevated acute-phase reactants (erythrocyte sedimentation rate or leukocyte count).

***Supporting evidence for a preceding streptococcal infection within the last 45 days: prolonged PR interval on electrocardiogram; elevated or rising antistreptolysin-O or other streptococcal antibody; positive throat culture results; positive result on rapid antigen test for group A streptococci; recent scarlet fever.

^aPatients may have polyarthritis (or only polyarthralgia or monoarthritis) and several (three or more) other minor manifestations, together with evidence of recent group A streptococcal infection. Some of these cases may later turn out to be rheumatic fever. It is prudent to consider them as cases of “probable rheumatic fever” (once other diagnoses are excluded), and regular secondary prophylaxis is advised. Such patients require close follow-up and regular heart examinations. This cautious approach is particularly suitable for patients in vulnerable age groups in high-incidence settings.

^bInfective endocarditis should be excluded.

^cCertain patients with recurrent attacks may not fulfill these criteria.

^dCongenital heart disease should be excluded.

course of oral penicillin for treatment of streptococcal pharyngitis and may be an alternative in countries with a low incidence of RF.³⁸

Clinical clues are not sufficient to differentiate viral from streptococcal pharyngitis, even for experienced clinicians. If the means are available, the streptococcal infection should be confirmed using a throat culture or rapid diagnostic antigen-detection test. The American Heart Association recommends that a negative antigen test result be confirmed by throat culture. This strategy is not appropriate in developing countries, where throat culture and serologic testing are not readily available. The elimination of positive throat culture results as a prerequisite for prescribing antibiotics for throat infections was followed by a significant reduction in the incidence of RF in Costa Rica, although a causal association could not be confirmed.³⁹ Although it is clear that all streptococcal pharyngitis should be treated with antibiotics and that the population in question and medical awareness regarding RF are fundamental for the prevention of the disease, there are conflicting data on whether school-based systematic screening and treatment of sore throats are cost effective, even in endemic areas.^{40,41} This uncertainty is explained in part by the fact that as many as one third of throat infections are asymptomatic.

TREATMENT OF ACUTE RHEUMATIC FEVER

Bed rest

Bed rest is traditionally advised in cases of ARF, although this recommendation is not based on clinical trial results. Once the symptoms subside, the patient should be progressively mobilized.

Antibiotic therapy

Patients with ARF should receive antibiotic therapy to eradicate GAS, regardless of whether pharyngitis is present at the time of diagnosis. Close associates and household contacts should be tested for streptococcus carriage and treated if positive.

Arthritis, fever, and rash

Most inflammatory ARF symptoms, including arthritis and fever, respond promptly to nonhormonal antiinflammatory agents. Aspirin (80 to 100 mg/kg/day in children and 4 to 8 g/day in adults) is the traditional choice and should be continued until all of the symptoms subside and levels of inflammatory markers normalize. Other NSAIDs can be used instead of aspirin, and naproxen has been reported to be effective and well tolerated. Erythema marginatum does not require treatment, although antihistamines may help alleviate pruritus.

Acute carditis

Patients with congestive heart failure and third-degree heart block must receive treatment for these complications. A 2003 Cochrane meta-analysis, updated in 2012, involving eight randomized controlled trials that involved 996 individuals with ARF observed no significant difference in the risk of cardiac disease between corticosteroid-treated and aspirin-treated groups at 1 year.⁴² Similarly, administration of intravenous immunoglobulin did not alter the evolution of ARF.⁴² There are no evidence-based treatment options for patients with acute carditis, and steroids are occasionally used in severe cases. The preference is to delay valve surgery until the carditis is inactive, but surgery may be necessary during the acute phase when heart failure due to regurgitant lesions cannot be managed with medications alone.

Sydenham chorea

Chorea is frequently mild and self-limiting, not requiring specific therapy. For prolonged or incapacitating cases, haloperidol, diazepam, and carbamazepine have all been reported to be effective. In one study, a group of 22 children with Sydenham chorea treated with prednisone exhibited a more rapid resolution of symptoms than 15 children given a placebo.⁴³

SECONDARY PREVENTION

The risk of a new ARF attack following a GAS infection is between approximately 25% and 75% for those with a history of previous RF. Thus patients with RF are at a high risk of recurrences and increased severity of the manifestations, including RHD. Recurrences can occur at any time but are most common in the first 2 years following the initial attack. Because streptococcal pharyngitis is often asymptomatic, secondary prevention requires continuous antimicrobial prophylaxis rather than treatment of the acute episodes of GAS pharyngitis. This treatment is indicated for any patient with a documented history of ARF or Sydenham chorea, or convincing evidence of RHD. Intramuscular penicillin appears to be more effective than oral penicillin in preventing recurrences.⁴⁴ Intramuscular injection of benzathine benzylpenicillin G is the regimen of choice (1.2 million units for children and adults weighing >27 kg and 600,000 units for those weighing <27 kg).²⁵ Alternative treatments are penicillin V (250 mg twice daily, orally) and sulfadiazine (0.5 g once daily, orally, for those weighing <27 kg and 1 g/day for those weighing >27 kg). Patients allergic to penicillin and sulfadiazine should be treated with 250 mg of erythromycin orally twice daily.²⁵ Several factors can influence the risk of RF recurrences, including patient age, the presence of RHD, the time elapsed from the previous attack, the number of previous episodes, the degree of crowding in the family, a family history of RF/RHD, the socioeconomic and educational status of the individual, the risk of streptococcal infection in the area, and the patient's occupation and place of employment (e.g., schoolteachers, physicians, and employees who work in crowded areas may be at higher risk). For high-risk patients and in high-risk areas, intramuscular penicillin G should be administered every 3 weeks or less, given that the levels of penicillin are low in the fourth week. Similarly, the duration of secondary prophylaxis should be individualized. The 2004 WHO guidelines for the duration of secondary prophylaxis are summarized in Table 111.3.

In a prospective study of 59 patients with ARF judged to be at a low risk of recurrence, secondary prophylaxis was not indicated and patients were closely followed during 3349 patient-months. Only two ARF episodes were observed in the study group, result suggesting that discontinuing ARF

TABLE 111.3
WHO guidelines for duration of secondary prophylaxis

Patient category	Duration of prophylaxis
No proven carditis	For 5 years following the previous attack or until 18 years of age (whichever is longer)
Carditis (mild mitral regurgitation or healed carditis)	For 10 years following the previous attack or until 25 years of age (whichever is longer)
More severe valvular disease	Lifelong
Following valve surgery	Lifelong

Note: These are only recommendations and must be modified as individual circumstances warrant.
 WHO, World Health Organization.
 Data from Rheumatic fever and rheumatic heart disease: report of a WHO expert consultation. World Health Organ Tech Rep Ser 2004;923:1-122.

prophylaxis may have a favorable risk-benefit ratio in patients who are at a low risk of recurrence and are kept under careful prospective surveillance.⁴⁵

The efficacy of secondary prophylaxis programs depends completely on patient compliance with the prescribed drug regimen. A prospective international study that involved 1790 patients demonstrated a prevalence of new ARF attacks of 0.45% among the patients who regularly received benzathine benzylpenicillin G compared with 11.5% in noncompliant patients.⁴⁶

Unfortunately, noncompliance is far from exceptional. In the Aboriginal communities of Australia, only one in five individuals with a history of ARF or RHD receives 80% or more of the scheduled doses.⁴⁷ The reasons for noncompliance include the painfulness and high frequency of injections, the long period of treatment, and the low socioeconomic and educational level of the patients.

Endocarditis prophylaxis

Patients with RHD should receive prophylactic antibiotics to prevent infective endocarditis when they undergo surgical procedures of the mouth (e.g., dental extractions), eyes, ears, nose, throat, or gastrointestinal and genitourinary tracts.⁴⁸

Vaccines

Efforts to produce an effective vaccine against streptococcal infections have been ongoing for more than three decades. Despite the advances that have been made in this field, no ideal vaccine is available. The major difficulties for researchers are the following: (1) The vaccines should not trigger autoimmunity or exacerbate the disease. (2) More than 130 GAS M-serotypes have been described, and nontypeable strains of GAS are equally capable of causing infection. New M-types are constantly emerging, and their association with disease varies greatly among regions. (3) The vaccine's epitope should be equally effective and safe in all HLA class II contexts. (4) The vaccine should produce lasting immune protection.

The increasing immunity to streptococcal infections that normally occurs with age indicates that the development of a vaccine is possible, and such a vaccine hopefully will be available in the future.

Reactive arthritis

■ ROBERT D. INMAN

- Reactive arthritis is the paradigm of a rheumatic disease in which genetic susceptibility interacts with an environmental trigger.
- Genetic elements that predispose to reactive arthritis include polymorphisms in class I MHC molecules and toll-like receptors.
- Reactive arthritis has microbial and immunologic features that suggest it is a *forme fruste* of septic arthritis.
- New concepts in the management of reactive arthritis—including antibiotics and biologics—are developing.

INTRODUCTION

Reactive arthritis (ReA) became operationally defined as a nonseptic arthritis that followed an extraarticular infection.¹ Although rheumatic fever itself would qualify for this definition, the concept became clinically associated with antecedent infections of the gastrointestinal and genitourinary tracts. In cases in which *Salmonella* or *Chlamydia* organisms were cultured from the respective sites, this construct provided a useful framework for understanding pathogenesis. But much of the clinical research in this area was hampered by uncertainties in disease definition. If the triggering pathogen could not be isolated from the gastrointestinal or genitourinary tract, would antecedent diarrhea or urethritis be sufficient for the diagnosis? Would there be antibody profiles with sufficient specificity to be considered as inclusion criteria for ReA? Would proliferation of immunoreactive cells from synovial fluid (in response to candidate bacterial antigens) carry diagnostic specificity? Challenges to these studies were also compounded by poorly defined diagnostic criteria for ReA and by changing nomenclature as the older term *Reiter syndrome* came to be replaced by *reactive arthritis*.

Extrapolating from rheumatic fever, a number of investigations addressed molecular mimicry as the basis of ReA. These studies sought to operationalize the recent discovery of HLA-B27 as a risk factor not only for ReA but also for ankylosing spondylitis (AS). Approaches to linking infection to disease included demonstration of sequence homology between B27 and arthritogenic pathogens, as well as the characterization of monoclonal antibodies and T-cell clones reacting with both B27 and the putative inciting organism.^{2,3} Some experimental models suggested that *Chlamydia* could break tolerance of self-B27.⁴ But rigorous proof that autoreactivity is the underlying mechanism in ReA remained difficult to obtain, and ReA remained a charter member of *seronegative* spondyloarthritis.

The report that phlogistic components of *Yersinia* and *Salmonella* could be recovered from synovial fluid of ReA patients suggested that, rather than autoimmunity acting as the operational event in chronic ReA, local persistence of microbial fragments could be the true culprit. The presence of such foreign material was demonstrated by immunofluorescence studies of synovial fluid and synovial tissues.⁵ These findings shifted the focus of investigators to address the structural basis of arthritogenicity. It was found that certain glycosylation patterns of foreign antigen appeared to correspond with the ability to induce experimental ReA by virtue of lingering as non-biodegradable fragments in the joint.⁶ Gas chromatography and mass spectrometry analysis of organisms can identify such patterns, but this approach has yet to be transferred into clinical practice.

INNATE IMMUNITY AND REACTIVE ARTHRITIS

For all the sophistication of adaptive immunity, with specificity and memory as its pinnacle achievements, it was recognized that the time required to

expand the T-cell and B-cell responses in the setting of acute infection could place the host at great peril. The concept of innate immunity as the first line of host defense was the province of students of leukocyte biology. The discovery of Toll-like receptors (TLRs) as the quintessential recognition elements of the innate immune system created an intense interest in defining the role of this family of receptors in infectious disease. There were, however, some conceptual hurdles in the path of linking TLRs to rheumatic diseases.

The first of these hurdles related to the apparent nonpolymorphic nature of the TLR, which posed a significant challenge in explaining the heterogeneity of susceptibility to ReA in target populations. The second was that self-nonsel self discrimination by the innate immune system was proposed to be perfect, unlike its forever failing counterpart in adaptive immunity. Both of these concepts have needed significant revision. There are, in fact, significant polymorphisms in the TLR families, and recent studies of epidemic ReA have demonstrated that nonsynonymous single nucleotide polymorphisms (SNPs) in TLR2 confer susceptibility to post-*Salmonella* ReA.⁷ The notion that TLRs are specific only for foreign determinants has been replaced by the recognition that mammalian nucleic acids, among other molecules, are ligands for certain TLRs; indeed, this concept has proved to be pivotal in current concepts of lupus pathogenesis.

These findings have broadened the landscape linking infection to arthritis. The hypothesis of microbial pathogenesis began from the conceptual starting line that disease mediated by infection resulted from viable microbes in the target organ. The discovery of the complex tango of receptor-ligand interactions involving TLRs led to the recognition that the inflammation arising as a consequence of infection requires neither a viable pathogen nor even the intact organism. Signaling events that can usher in damaging inflammation call only for fragments of the pathogen, such as lipopolysaccharide or peptidoglycan, to interact with TLRs on host cells. This has been borne out in several experimental models of arthritis. The B27 transgenic rat expresses a number of features that recapitulate spondyloarthritis (SpA) in patients, including arthritis, dermatitis, and enteritis.⁸ These features are dramatically attenuated if the animal is raised in a germfree environment.⁹ Reestablishing the clinical features of SpA in this model does not require a gut infection in the usual sense. Rather, the animal need only be challenged with a gut commensal, *Bacteroides*, which normally would not be counted among the arthritogenic pathogens.

Thus the gut's being populated, not infected, with commensal organisms creates the immunologic platform on which arthritis can proceed. The mouse deficient in interleukin-1 receptor antagonist (IL-1Ra) is genetically programmed to develop an aggressive polyarthritis. This propensity, too, is completely abrogated if the animal is raised germ free.¹⁰ But to reestablish the arthritis in the germfree setting requires no intact organism at all. A TLR ligand alone will do quite nicely. These studies have also demonstrated that TLR signaling at the gut level can have very disparate effects on arthritis, with TLR4 signaling playing an exacerbating role and TLR2 signaling playing a modulatory role.

When viewed in the context of concurrent genetic polymorphisms not only in TLR but also in class I major histocompatibility complex and IL-23R, the infectious link between gut and joint has become intriguingly complex. This situation has become clinically relevant with the recognition that TLR2 genetic polymorphisms predispose to post-*Salmonella* ReA. The importance of the gut as the site of triggering events has been supported not only by the recognition that the same genetic variants confer susceptibility to AS and to Crohn disease (CD) but also that subclinical inflammation and upregulation of IL-23 expression is present in gut tissues of AS patients.^{11,12} Hematologists in search of the cause of pernicious anemia might have probed the bone marrow ad infinitum without realizing that the answer lay in the gut. Are rheumatologists destined to learn the same lesson?

Fig. 112.1 Toll-like receptors in the pathogenesis of reactive arthritis (ReA). LPS, lipopolysaccharide; TLR, Toll-like receptor. (From Inman RD. *Reactive arthritis—back to the future. Rheumatologist* 2010;4:24-33.)

Too much immunity or too little?

The underlying assumption in the molecular mimicry theories, exemplified by the studies of rheumatic fever, is that the host immune response to infection is *overactive* in nonseptic sequelae like ReA. But there are intriguing clues that host defenses might be diminished rather than amplified in patients with ReA. The cytokine profiles of ReA patients suggest downregulation of proinflammatory cytokines rather than upregulation.¹³ These changes include a decrease in levels of tumor necrosis factor- α (TNF- α) and interferon- γ (IFN- γ), cytokines normally thought to be deleterious rather than beneficial cytokines with respect to arthritis. The role of cytokine dysregulation in disease etiology is borne out in experimental ReA.¹⁴ Animals that are susceptible to *Chlamydia*-induced arthritis have *diminished* rather than enhanced production of TNF- α and IFN- γ within the joint. This appears to relate to impaired capacity of host clearance of the organism in susceptible strains of animals. Of interest, this genetically defined cytokine signature can be dramatically altered by exposure to heavy metals, which suggests that other environmental factors may come into play in the dynamics of ReA in the clinical setting.¹⁵

Recent studies in CD have supported the role of defective host immune response to foreign organisms in immunopathogenesis. Genetic susceptibility to CD has been related to polymorphisms in the *CARD15* gene, but the implicated SNPs suggest a loss-of-function process that would predict diminished, not enhanced, elaboration of TNF- α . This situation seems counterintuitive in a disease that is marked by TNF-mediated inflammation and that is responsive to anti-TNF agents. Recent studies have shed light on this paradox.¹⁶ Macrophage function in CD is indeed diminished, with impaired generation of proinflammatory cytokines, because of lysosomal degradation of precursor molecules, which impairs their egress to the secretory pathways of the macrophage. The net effect of this cytokine signature is diminished inflammatory response to pathogens, with persistence of the organism being the consequence. Thus the model for CD, as that for ReA, is undergoing a conceptual change that suggests therapeutic enhancement, rather than diminution, of host immune responses as a strategy for intervention.

Have we thus come full circle in considering the role of infection in ReA? With the expanded knowledge of innate immunity in arthritis and autoimmunity, and the recognition that TLRs function as gatekeepers of adaptive immunity by upregulation of costimulatory molecules, the microbial aspects of ReA and CD have begun to be clarified. The genetic complexity of CD revealed in recent genomewide association studies suggests that modulation of host-microbial interactions is a complex and changing story. But more pieces of this challenging jigsaw puzzle are now in place.

Self-nonspecific complexities arising

In the original formulation of the underlying principles of the innate immune response, perfect self-nonspecific discrimination was proposed as the one of the cardinal features since the pathogen-associated molecular patterns (PAMPs) recognized by host innate immune receptors were so different from endogenous host ligands that a case of mistaken identity was never allowed. A PAMP was the molecular passport of an alien. But what happens in the event that an alien not only has invaded our home and native land, but has become enculturated and fully assimilated into the society? Such is the case with the bacterial symbionts of antiquity that invaded eukaryotic cells, set up distinct societies, and in time became mitochondria. But a genetic footprint of this event has been left behind: our mitochondrial DNA retains significant sequences of bacterial DNA.¹⁷ With respect to immune recognition, this is far more profound, and more unnerving, than molecular mimicry of host and microbial determinants. This is molecular *identity* of host and microbial determinants.

What, then, would transpire if the DNA were released systemically, as might occur following trauma? This might occasion a response that is indistinguishable from sepsis, which seems unlikely. Yet that is precisely what occurs. The binding of mitochondrial DNA to TLR9 on the surface of neutrophils initiates activation of neutrophils and release of IL-8 in a way that looks just like an infection.¹⁸ Indeed, infusion of mitochondrial DNA alone initiates an intense pneumonitis similar to that seen in the systemic inflammatory response syndrome that occurs after trauma. This recognition is changing the landscape of the concept of infection. Perhaps the enemy has been lurking within all along. With respect to host immune response, perhaps we have met the enemy and it is us (Fig. 112.1).

Because our thinking of self-nonspecific proved in retrospect to be simplistic, and the gap between infection and trauma begins to narrow, potential new scenarios arise in the pathogenesis of inflammatory joint disease. Could exacerbation of AS after trauma reflect such processes? Could chronic inflammatory events in the skin, with local tissue injury, set the stage for psoriatic arthritis? Could the mucosal injury of *Salmonella* gastroenteritis or *Chlamydia* urethritis invoke these pathways? Could all arthritis be reactive?

CHLAMYDIA-INDUCED REACTIVE ARTHRITIS

As stated earlier, ReA is operationally defined as an inflammatory arthritis preceded by an extraarticular infection, most commonly with the enteric pathogens *Salmonella*, *Yersinia*, and *Campylobacter* or the oculogenital pathogen *Chlamydia*.¹⁹ By virtue of HLA-B27 association, pattern of joint

involvement, and the absence of rheumatoid factor, ReA is classified as a part of the spectrum of SpA. However, there are distinct differences between ReA and the classical spondyloarthritis such as AS, notably a lower association with HLA-B27²⁰ and an established link between a prior infection with the aforementioned bacteria and the onset of arthritis. Moreover, it is becoming clear that post-enteritis and post-*Chlamydia* ReA are distinct entities in that viable organisms can be detected in the joints of patients with *Chlamydia*-induced ReA (CiReA), but not those of patients with post-enteritis ReA.²¹ CiReA represents the majority of cases of ReA. Between 4% and 15% of those with genital chlamydial infections subsequently develop arthritis, which accounts for over half of all ReA cases. Given the high prevalence of chlamydial genital tract infections, it has been proposed that the incidence of CiReA may rival that of rheumatoid arthritis.²² Furthermore, many undifferentiated spondyloarthritis have been proposed to be undiagnosed ReA. Thus CiReA represents a significantly understudied disease with a measurable physical and economic burden.²³

Reactive arthritis: the noncanonical septic arthritis

The term *reactive arthritis* describes how this disease was traditionally viewed as a nonseptic, autoimmune reaction occurring in the joint in response to an extraarticular bacterial infection.^{24,29} This notion was based on the fact that no pathogen could be cultured from the arthritic joint despite detection of arthritis-associated bacteria at other sites in the body. Surprisingly, extensive searching for the bacterial antigens responsible for adaptive immunity-mediated pathology has not yielded conclusive results to date. To further confound the autoimmunity-mediated hypotheses for ReA, it was discovered that *Chlamydia* organisms are present in the joint, albeit in an aberrant but viable state, through the use of nucleic acid detection methods and electron microscopy.

The possibility that CiReA is driven not by a reactive autoimmune process but rather by the infection of nonimmune cells *in situ* has paralleled a paradigm shift establishing the mechanism of tissue damage during chlamydial infections in general. Initially the immunologic paradigm proposed that tissue damage results from the aberrant activation of the adaptive immune system through delayed-type hypersensitivity or autoimmunity.²⁵ An alternative cellular paradigm postulates that chlamydial pathogenesis is driven by an inflammatory response propagated by sustained infection of nonimmune cells whereby ongoing release of inflammatory mediators and subsequent recruitment of inflammatory cells causes tissue damage.²⁶ Since *Chlamydia* is known to infect fibroblast-like synoviocytes,²⁷ could the cellular paradigm hold true in CiReA?

With the identification of viable *Chlamydia* organisms in the joint, a contradiction arises regarding the classification and nomenclature of CiReA in terms of underlying clinical and pathologic features. Figure 112.2

illustrates this concept, with ReA holding a midpoint between SpA and septic arthritis. In support of the concept of CiReA as a septic arthritis, a recent clinical trial demonstrated that combination antibiotics could alter the course of ReA.²⁸ In addition, the immunopathogenesis of CiReA recapitulates that seen in experimental septic arthritis with regard to mediators of susceptibility and the role of the immune system^{29,30} (see Fig. 112.2).

The classification of CiReA as a septic arthritis necessitates a better understanding of bacterial colonization of the joint. After primary infection in both humans and animals, *Chlamydia* is known to spread throughout the body via monocytic cells³¹ to a diverse group of tissues, including spleen, liver, peritoneum, and lungs.³² In many of these tissues *Chlamydia* is cleared, so why is it that organisms are found in the joint long after initial infection? The traditional hypothesis suggests that the joint provides an immunoprivileged site; however, immune cells can be found in the joint in either the healthy or the arthritic state. One extension of this theory proposes that it is the hypoxic environment of the inflamed joint³³ that creates an immunoprivileged microenvironment. This idea stems from the fact that the natural site of infection for *Chlamydia*, the genital tract, is relatively hypoxic and that *Chlamydia* thrives under hypoxic conditions.³⁴ It appears that *Chlamydia* may have adapted to growth under such conditions, because the organism actively manipulates hypoxia-inducible factor 1 (HIF-1).³⁵ Additionally, both bacteriocidal cytokines such as IFN- γ and antibiotics³⁶ have reduced efficacy under hypoxic conditions, which provides the rationale for chlamydial escape from these mechanisms of control within the joint.

Chlamydial persistence: pathogenicity or symbiosis?

Another incompletely explained aspect of host-pathogen interaction during CiReA is the observation that *Chlamydia* adopts an atypical, persistent state within the joint. *Chlamydia* is an obligate intracellular pathogen that exist in two distinct states during its life cycle: the extracellular, infectious elementary body and the intracellular, replicative reticulate body. When appropriate stress is applied during the intracellular stage, such as IFN- γ exposure, antibiotic treatment, or infection of monocytic cells, *Chlamydia* enters a nonreplicative and unculturable but viable persistent state.³⁷ The persistent state differs from the normal intracellular state in that *Chlamydia* organisms fail to divide or differentiate into infectious particles, have a reduced metabolism, and are immunoevasive.³⁸

Persistent *Chlamydia* organisms in CiReA were originally detected through microscopy or polymerase chain reaction (PCR) analysis and could not be cultured from synovial biopsy specimens.³⁹ It is now possible to accurately identify *Chlamydia* with a persistent phenotype in CiReA using quantitative PCR analysis, because these cells display a unique gene expression profile.⁴⁰ The recognition of persistent *Chlamydia* in ReA represents an important advance in our understanding of this disease but leaves unanswered key questions with respect to pathogenesis.

Is persistent *Chlamydia* the cause of ReA or the effect of host-pathogen adaptation? A mechanistic hypothesis to address *Chlamydia* as the instigator of ReA postulates that persistent *Chlamydia* organisms provide a continuous source of bacterial components to stimulate the immune system, which results in chronic inflammation and tissue damage.⁴¹ These components could be PAMPs that stimulate host innate receptors or adaptive immune responses against microbial antigens. On the other hand, it is equally plausible that persistence represents the host's best attempt at controlling *Chlamydia*, which has developed specialized mechanisms to avoid the immune response, especially through the establishment of the immunoevasive persistent state. In support of this theory, chronic chlamydial infection elicits little immune stimulation relative to that seen during acute infection.⁴² This latter theory also provides the rationale for the arthritic flares seen commonly in ReA because chlamydial escape from persistence could result in an acute inflammatory event. The basic understanding of chlamydial persistence is in its early stages, and an emphasis needs to be placed on understanding the role of this phenomenon in the pathogenesis of CiReA. Thus clinical ReA studies need to address chlamydial state concurrently with joint inflammation, and animal models need to address the temporal relationship between persistence and arthritis.

Mediators of susceptibility to *Chlamydia*-induced reactive arthritis

Up to 80% of chlamydial infections are asymptomatic.⁴³ This poses significant hurdles in attempting to link clinical evidence of infection with subsequent ReA, but clearly only a few infected individuals go on to develop ReA, for reasons not yet defined. Factors that contribute to the increased virulence of an infection include pathogen, host, and environmental variation.

Fig. 112.2 The interface of septic and reactive arthritis (ReA). CiReA, *Chlamydia*-induced reactive arthritis. (From Gracey E, Inman RD. *Chlamydia-induced ReA: immune imbalances and persistent pathogens*. *Nat Rev Rheumatol* 2011;8:55-9.)

The most commonly observed variability in *Chlamydia* relates to the outer membrane proteins that dictate chlamydial biovar. This variation is associated with tissue tropism rather than virulence; however, one study did detect ocular biovars more commonly than genital biovars in ReA.⁴⁴ A limited number of studies have addressed non-biovar-related variance as a determinant of pathogenicity,⁴⁵ yet the effect of this variance on human infection or CiReA remains to be determined. From a broader perspective, a stable host-pathogen interaction is indicated by the consistent rates of *Chlamydia*-related disease⁴⁶ compared with the fluctuating temporal incidence of diseases caused by highly mutable pathogens such as influenza virus. This suggests that alterations in chlamydial pathogenicity are uncommon. Environmental factors are also known to affect chlamydial infections. Clinically, repeated chlamydial infections have been associated with increased genital tract abnormality,⁴⁷ but whether repeated infections are required for the development of CiReA remains unknown. In practice this issue is rarely addressed because diagnostic tests for *Chlamydia* do not distinguish between repeat infections and chronic infections with the same pathogen.⁴⁸ Another potential environmental factor is heavy metal exposure. Experimentally, it has been shown that exposure to heavy metals sensitizes otherwise-resistant animals to CiReA.⁴⁹ Heavy metal-induced sensitization correlates with the suppression of the inflammatory cytokines IFN- γ and TNF- α , which raises the question of an immune imbalance as a mediator of susceptibility to CiReA.

Most studies examining mediators of susceptibility to chlamydial sequelae focus on host genetic variability—in particular, differences in the genes determining immune response. A robust type 1 (classical) inflammatory response is crucial for the control of *Chlamydia*, whereas an enhanced type 2 (alternative) inflammatory response is associated with susceptibility to infection (Fig. 112.3). This has been demonstrated in animal models in

which deficiency of type 1 cytokines, such as IL-12 or IFN- γ , influences susceptibility to chlamydial infection, whereas deficiency of type 2 cytokines, such as IL-10, influences resistance.⁵⁰

Furthermore, it has been shown that high synovial IFN- γ and TNF- α levels correlate with resistance to experimental induction of CiReA.⁵¹ The protective effect of a type 1 response during chlamydial infection of animals has been recapitulated in human studies in which sequelae are associated with higher type 2 cytokine responses.⁵² Additionally, an attenuated type 1 response is seen in patients with SpA,⁵³ manifested as an impaired IFN- γ -induced gene expression profile.⁵⁴ Although there are few studies in CiReA, the trends appear to be consistent, with patients who experience prolonged ReA expressing lower IFN- γ than those who rapidly overcome ReA.⁵⁵ Another study demonstrated the IL-10/IL-12 balance to be crucial in preventing ReA.⁵⁶

Importance of innate immunity in *Chlamydia*-induced reactive arthritis

If susceptibility to CiReA is determined by a disruption in the yin-yang balance of type 1 and type 2 inflammatory responses, then at which point during an inflammatory response does such an imbalance have an effect? The immune system is comprised of two distinct arms, the germline-encoded, rapidly responding innate immune response, and the delayed but highly specific adaptive immune response. Both systems can be polarized during a type 1- or type 2-dominant response. CD4⁺ T cells can be polarized into the well-defined helper T 1 (Th1) and Th2 phenotypes, which have traditionally defined type 1 and type 2 responses. Th1 cells are crucial for eliminating chlamydial infections⁵⁷; however, an effective immune response to *Chlamydia*, and resistance to CiReA, is associated

Fig. 112.3 The role of macrophages in *Chlamydia*-induced arthritis. IFN, interferon; Th, helper T cell. (From Gracey E, Inman RD. Chlamydia-induced ReA: immune imbalances and persistent pathogens. *Nat Rev Rheumatol* 2011;8:55-9.)

with a robust type 1 cytokine response as early as 3 days after infection.^{50,58} These temporal kinetics exclude the adaptive immune system as the defining process in early resistance versus susceptibility to *Chlamydia*. But which cells of the innate immune response might cause a disrupted inflammatory balance and how might such cells be affected by this alteration?

Research into the innate immune response during *Chlamydia* infection has been somewhat neglected because the primary focus in chlamydial research has been on vaccine development. Yet many innate immune cells have been shown to play important roles. NK cells have been implicated in providing an early protective effect though IFN- γ release,⁵⁹ an effect that is also mediated by NKT cells during CiReA.⁶⁰ Neutrophils, on the other hand, appear to have a dual role in that they reduce early excessive chlamydial growth,⁶¹ yet excessive activation can itself contribute to tissue damage, including CiReA.⁶² Another innate cell type shown to be important in chlamydial infection is the macrophage, and macrophage depletion greatly enhances infection progression.⁶³

Macrophages are a heterogeneous group of related cells ranging from aggressive proinflammatory macrophages to passive tissue-resident macrophages. Tissue-resident macrophages comprise up to 15% of all cells in healthy tissue and up to 20% of synovocytes.⁶⁴ Thus the primary role of the macrophage should be viewed as that of a homeostatic local resident cell rather than an aggressive innate immune effector. Tissue-resident macrophages tend to be antiinflammatory and have recently been shown to maintain their numbers through proliferation of tissue-resident macrophages.⁶⁵ Inflammatory macrophage populations, on the other hand, rarely exist in healthy tissue and appear on the scene through recruitment and activation of blood monocytes.⁶⁵

A classification system has been devised to delineate polarized macrophages based on phenotype and function, encompassing a spectrum ranging from the classically activated or inflammatory (M1) macrophage to the homeostatic or alternatively activated (M2) macrophage.⁶⁶ This classification system was based on analogy with the Th1/Th2 paradigm in which polarization to M1 is induced by a type 1 inflammatory environment, such as by IFN- γ , and M2 is induced by an IL-10- or IL-4-containing environment. Furthermore, the existence of Foxp3+ regulatory macrophages has recently been demonstrated, akin to the identification of Foxp3+ regulatory T cells.⁶⁷ A key distinction exists between macrophage and Th-cell polarization in that macrophage polarization is highly plastic whereas the differentiation of T cells is somewhat rigid.⁶⁸ This plasticity serves host defense when one considers the role of the innate immune system, which is to respond rapidly to alterations in the immediate environment.

In many biologic systems a dynamic balance exists between opposing mechanisms, as is the case with macrophage polarization. Alterations in this balance, either endogenous or exogenous, are associated with certain pathologic processes, but often it can be hard to ascertain whether the polarized state is cause or effect. Differential macrophage polarization can be demonstrated in rheumatic diseases, with rheumatoid arthritis associated with an M1 dominance and SpA with an M2 dominance.⁶⁹ Further, a robust M1 response is essential for the control of intracellular pathogens, and it is recognized that a deficient M1 response facilitates uncontrolled acute intracellular bacterial infections.⁷⁰ Certain intracellular bacteria, such as *Francisella*, have been shown to induce M2 polarization in macrophages, which results in prolonged bacterial survival.⁷¹ *Chlamydia* is known to infect macrophages, but how *Chlamydia* can survive in differentially polarized macrophages or whether *Chlamydia* is capable of such immune subversion remains unknown (see Fig. 112.3).

Macrophages as key players in *Chlamydia*-induced reactive arthritis

Given the importance of the macrophage in chlamydial infections and susceptibility correlating with a deficient early type 1 response, it is surprising that more is not known about macrophage polarization in the setting of chlamydial infections, especially in the microenvironment of the joint during CiReA. There are, however, indicators that M1 macrophages control *Chlamydia*⁷² and that M2 may be permissive to chlamydial growth⁷³; yet control of *Chlamydia* has traditionally been measured as a reduction in culturable organisms, which is also the hallmark of persistence. An important goal is to validate the observation of M2 macrophage dominance in SpA and to determine if this alteration in macrophage phenotype is also present in CiReA. It is conceivable that individuals with an M2 dominance are less able to control chlamydial infections and thus are more susceptible to *Chlamydia*-associated inflammation of the joints. Additionally, it is plausible that joints are particularly sensitive to M2 polarization given that IFN- γ has reduced activity under hypoxic conditions.

BOX 112.1 PRELIMINARY CLASSIFICATION CRITERIA FOR REACTIVE ARTHRITIS

Major criteria

1. Arthritis, with two of three of the following findings:
 - Asymmetric
 - Monoarthritis or oligoarthritis
 - Affecting predominantly lower limbs
2. Preceding symptomatic infection, with one or two of the following findings:
 - Enteritis (diarrhea for at least 1 day, 3 days to 6 weeks before the onset of arthritis)
 - Urethritis (dysuria or discharge for at least 1 day, 3 days to 6 weeks before the onset of arthritis)

Minor criteria (at least one of the following)

1. Evidence of triggering infection
 - Positive nucleic acid amplification test in the morning urine or urethral/cervical swab for *Chlamydia trachomatis*
 - Positive stool culture for enteric pathogens associated with reactive arthritis
2. Evidence of persistent synovial infection (positive result on immunohistologic analysis or polymerase chain reaction assay for *Chlamydia*)

Definition of reactive arthritis

Definite reactive arthritis: Both major criteria and one relevant minor criterion

Probable reactive arthritis: Both major criteria but no relevant minor criteria or major criteria and one or more minor criteria

Exclusion criteria

Other causes for acute arthritis

Modified from Braun J, Kingsley G, van der Heijde D, et al. On the difficulties of establishing a consensus on the definition of and diagnostic investigations for reactive arthritis: results and discussion of a questionnaire prepared for the 4th International Workshop on Reactive Arthritis, Berlin, Germany, July 3-6, 1999. *J Rheumatol* 2000;27:2185-92.

CLASSIFICATION CRITERIA

Early approaches to the development of criteria for ReA relied on clinical symptoms such as preceding symptomatic infection or extraarticular manifestations. Proposed criteria for “Reiter syndrome” that address arthritis in association with urethritis or cervicitis may not apply to ReA occurring after other infections such as enteritis. Specifying a duration of arthritis of at least 1 month excludes the mildest forms of ReA. The need to include inflammatory axial pain and to identify ReA-triggering microbes was emphasized.^{74,75} A consensus was achieved in 1999 that use of the term *reactive arthritis* should be confined to patients who have clinical features and in whom the preceding infection is caused by a microbe that commonly associates with ReA, and this yielded preliminary, but not validated, classification criteria for ReA (Box 112.1).

The primary focus of infection is through the mucosal membrane, usually in the gut or in the urogenital tract. *Chlamydia trachomatis* is by far the most common cause of genital infection, but infections with other organisms such as *Ureaplasma urealyticum* are associated.^{76,77} *Neisseria gonorrhoeae* can cause septic and sterile arthritis, but its role as a triggering agent of ReA is not well established. Infection with *Mycoplasma genitalium* is connected with urethritis, but its role as an independent trigger (in the absence of *Chlamydia* infection) is not settled. *Chlamydia (Chlamydophila) pneumoniae*, a respiratory pathogen, can be involved in about 10% of patients.⁷⁸

In the gastrointestinal tract, the common microbes that are associated with ReA include *Yersinia*, *Salmonella*, *Shigella*, and *Campylobacter*. Previously, *Shigella flexneri* was the only *Shigella* species that had been associated with ReA. However, according to a large epidemiologic survey in Finland, *Shigella sonnei* and *Shigella dysenteriae* can also trigger ReA.⁷⁹ Other infections less frequently diagnosed in association with ReA are infections with *Campylobacter lari*, *Chlamydia psittaci*, and *Clostridium difficile*.⁸⁰

The list of potential triggering agents in ReA is gradually growing (Box 112.2). Bacteria belonging to the normal gut flora (e.g., *Escherichia coli*) have only occasionally been connected with ReA. However, epidemiologic data from Denmark^{81,82} show that a considerable number of patients (1% to 16%) report arthralgia and even arthritis in association with gut infection caused by diarrheagenic strains of *E. coli* identified in the stools.

GENETIC FACTORS

HLA-B27 is the hallmark of the genetic component of spondyloarthritides, and about 90% of patients with AS carry this antigen. The first

hospital-based reports of patients with ReA showed 60% to 80% positivity for HLA-B27. HLA-B27 is associated with a more severe arthritis and the occurrence of extraarticular features and predicts a prolonged disease course.⁸³⁻⁸⁵ By contrast, in population-based studies, the disease is usually mild, oligoarticular, or polyarticular in patients with only a slight or no increase in HLA-B27.⁸⁶ Polymorphisms of TLR2 were reported to be associated with post-*Salmonella* ReA, which suggests that genetic alterations in innate immunity may set the stage for late sequelae of enteric infections.⁷

EPIDEMIOLOGY

The data on the incidence and prevalence of ReA are influenced by the prevalence of triggering infections in the community, genetic susceptibility (frequency of the HLA-B27 gene) in the population, and the criteria applied to diagnose ReA. Much of the epidemiologic data concern the incidence of ReA after infection and estimate that 1% to 15% of patients with ReA are found to have a prior infection. Enterically triggered ReA occurs most commonly after outbreaks caused by gastroenteritis, whereas sexually acquired ReA is endemic.⁸⁷ In epidemiologic studies, nationwide laboratory registers of pathogenic microbial isolations have proved to be helpful.

In California the Foodborne Diseases Active Surveillance Network (FoodNet), covering a population of 2.2 million, collects data on laboratory-confirmed infections with enteric pathogens. Of the 1454 infections reported from 1998 to 1999, 52% were due to *Campylobacter*; 22% due to *Salmonella*, 15% due to *Shigella*, 2% due to diarrheagenic *E. coli* O157:H7, and 2% due to *Yersinia*.⁸⁸ According to results of a questionnaire, newly developed musculoskeletal symptoms were reported by 2.1% of the individuals, most of whom had *Campylobacter* infection.

Epidemiologic data from both the United States⁸⁹ and Denmark⁹⁰ show that 10% to 23% of patients report arthralgia and 13% report arthritis in association with gut infection, most frequently in association with *Yersinia* and *Salmonella* infections. These figures are applicable only to the Western world, in which background rates of gastrointestinal tract infections are low. Microbial contamination of drinking water is a common problem and a major source of microbial pathogens in developing countries, where about half of asymptomatic patients can carry enteric pathogens in the stools. Despite the microbial load, a prevalence study in rural western India disclosed no cases of well-defined ReA in the population of 4092 adults examined.⁹¹

There are only a few population-based studies examining the annual whole-population incidence of ReA, most conducted in Scandinavia. The total incidence has been estimated to be 10 to 30 per 100,000.^{89,92,93}

Campylobacter is the most important infective organism to cause gastroenteritis. In Finland and the United States, the annual incidences of ReA due to *Campylobacter* infection were 4.3 and 2.1 per 100,000, respectively.^{89,94} The U.S. data suggested an incidence of 1.4 per 100,000 after *Salmonella* infections. Tourism can change the epidemiologic data. In the West, *Shigella* infections are uncommon and are usually imported. The incidence of *Shigella*-induced ReA in Finland was 1.3 per 100,000,^{79,84} and all infections were acquired abroad.

Single-source epidemics, which give better information regarding the spectrum and severity of the diseases, have been reported in association with

Fig. 112.4 A patient with a swollen knee.

Fig. 112.5 A patient with acute reactive arthritis in the feet. Stool culture was positive for *Campylobacter jejuni*.

Yersinia enterocolitica, *Yersinia pseudotuberculosis*, *Campylobacter jejuni*, *Shigella flexneri*, and *Salmonella enterica* infections.^{95,96} The frequency of ReA varies greatly among these studies (from 0% to 29%) with low proportions associated with HLA-B27 positivity.⁹⁵ The clinical picture of ReA at the population level is milder, and only a minority of patients visit their physicians.

CLINICAL FEATURES

Infection may be the cause of acute joint symptoms in 9% to 18% of patients with inflammatory joint disease of less than 6 months' duration.⁹⁷ (see Box 112.1). Thus patients with ReA comprise about 10% of those who come to early synovitis clinics.⁹⁸ The clinical features of ReA are those of SpA, with arthritis the most frequent single manifestation. The patients are usually young adults (mean age, 30 to 40 years); in children the disease is uncommon and generally preceded by gastroenteritis. Male and female patients have a similar risk of ReA induced by gastrointestinal tract infection, whereas ReA triggered by *C. trachomatis* is more frequent in males. There is usually a lag of 1 to 4 weeks from the start of infection to the onset of musculoskeletal symptoms. The triggering infection can also be asymptomatic and hence go unrecognized.

Arthritis

The typical clinical feature of arthritis is asymmetric oligoarthritis, often in large joints of the lower extremities (Fig. 112.4). About 50% of patients have upper limb arthritis, and mild polyarticular small joint arthritis (Fig. 112.5) also occurs. Patients can also have dactylitis (Fig. 112.6). About 30% of patients have acute inflammatory low back pain, typically worse during the night, that radiates to the buttocks.

Extraarticular features

Patients frequently have extraarticular inflammatory symptoms and signs (Table 112.1).^{83,99} Enthesitis or bursitis can occur either in association with arthritis or as the only reactive complication. Other extraarticular features, common to other spondyloarthritides, include eye symptoms, usually conjunctivitis and less frequently acute anterior uveitis, and various skin symptoms, such as pustular eruption erythema nodosum (Fig. 112.7) and keratoderma blennorrhagicum, which is a pustular skin lesion usually observed on the soles of the feet. Circinate balanitis is most frequently associated with *Chlamydia* arthritis but can also occur in ReA from another cause. Erythema nodosum is usually associated with *Yersinia* infection and is more frequent in women. In addition to gut symptoms directly associated with gut infection, patients can have (often asymptomatic) chronic gut inflammation, mostly an aphthous colitis or terminal ileitis or microscopic gut inflammation. In most cases these conditions are benign, but they can herald the chronicity of arthritis.

LABORATORY TESTING

Presence of the typical clinical picture suggests the diagnosis of ReA, but the diagnosis is most confidently made if the triggering infection can be demonstrated by isolation of the microbe. Most of the genital infections are asymptomatic,¹⁰⁰ with a high suspicion of *Chlamydia* infection leading to the first test to detect *C. trachomatis* in the urogenital tract. The test of choice is examination of the first portion of the morning urine by nucleic acid amplification, because it is more convenient and results are comparable to

those with urogenital swab testing. Evidence of *Chlamydia* in the joint by PCR assay is diagnostic, but the methods used to test synovial samples have not been validated.

During the acute phase of enteric infections isolation is usually possible from the stools. However, by the time arthritic complications appear the patient may have already recovered from the gastroenteritis and the microbe may no longer be detectable in the feces. *Salmonella* and *Yersinia* infections are usually associated with a strong antibody response that suggests a diagnosis of ReA. There are no international standards for these tests, and the techniques vary greatly. Serologic methods include the classic agglutination tests (by the Widal technique), immunoblotting, hemagglutination, radioimmunoassay, and immunofluorescence tests. None of these techniques has gained general acceptance in clinical practice. The use of serologic testing (complement fixation, microimmunofluorescence, enzyme immunoassay) for the diagnosis of *C. trachomatis* infection is useful in upper genital tract infections and seroepidemiologic studies but not in lower urinary tract infections, which do not necessarily elicit a systemic antibody response. A degree of serologic cross-reactivity between *C. trachomatis* and *Chlamydia pneumoniae* complicates application of these tests, as well does the

Fig. 112.6 Dactylitis in a patient with reactive arthritis induced by *Chlamydia trachomatis*.

persistence of antibodies, which prevents distinction between past and present infection. Microimmunofluorescence serologic analysis, which is commonly used for diagnosis of *C. pneumoniae* infection, is not optimal because false-negative and false-positive results are frequently obtained. In only about 60% of patients with clinically diagnosed ReA can evidence of previous infection be detected by means of serologic testing and appropriate culture of urogenital or stool samples.¹⁰¹

A substantial proportion of infections are asymptomatic or associated with only minor symptoms, which can hinder the diagnosis. It is also not uncommon for the symptoms of the infection to have subsided when the patient comes to the physician. There are also infections—for example, those due to *Shigella*—for which no reliable serologic detection methods exist. Among the routine laboratory tests, erythrocyte sedimentation rate and C-reactive values are usually elevated. Synovial fluid leukocyte count can range between 2000 and 64,000/mm³. None of these laboratory tests is specific for ReA. HLA-B27 testing has little value, with a low posttest probability.¹⁰² Synovial fluid should always be cultured as the definitive test to distinguish between septic arthritis and ReA. Other rheumatic conditions, such as Lyme arthritis, gout, rheumatoid arthritis, viral arthritides, and osteoarthritis, should be excluded on the basis of the clinical picture and relevant laboratory test results.

NATURAL HISTORY

The average duration of acute ReA is 3 to 5 months, and about 15% of patients develop chronic sequelae (lasting longer than 6 months) or proceed into chronic SpA.⁸³ In about 4% of patients with *Yersinia* arthritis, 19% of those with *Salmonella* arthritis, 19% of those with *Shigella* arthritis, and 17% of those with *Chlamydia* arthritis, the disease extends longer than a year.⁸⁰ In some studies, chronicity has been reported in a vast majority of patients with the arthritis–urethritis–eye symptom triad.⁸⁰

After the acute episode, mild joint pain or enthesopathy is common. Also, one third of patients have occasional attacks of low back pain. Recurrent episodes of acute ReA seldom occur in patients with previous *Yersinia* arthritis but are more frequent in patients with previous *Salmonella*-, *Shigella*-, or *Chlamydia*-induced arthritis. Depending on the triggering infection and the follow-up time, chronic arthritis is observed in 2% to 18%, sacroiliitis in 14% to 49%, and definite AS in 12% to 26% of patients (Table 112.2).

Factors determining the progression of acute ReA to chronic SpA are not completely known, but they include the type of infection, the presence of HLA-B27, a family history of SpA or AS, and the presence of chronic gut inflammation. Patients with ReA triggered by urogenital infection seem to be more vulnerable to recurrent urethritides and, consequently, recurrent episodes of ReA. It is still uncertain to what extent ReA contributes to the development of sacroiliitis or AS or whether sacroiliac changes would have been proceeding in a patient with genetic predisposition to axial SpA even in the absence of intervening ReA (see Table 112.2).

ATYPICAL ASPECTS OF REACTIVE ARTHRITIS

SAPHO

One ongoing controversy in the field of ReA is whether SpA should include the clinical syndrome called SAPHO—synovitis, acne, pustulosis, hyperostosis, and osteitis.¹⁰³ The terms from which the acronym SAPHO is derived accurately describe its clinical features. In addition to synovitis, both hyperostosis and osteitis are seen. The most common sites of involvement are on the anterior chest wall—in particular, the clavicles, sternum, and sternoclavicular joints. Symptoms consistent with an SpA include a lower extremity oligoarthritis including the knees, hips, and ankles. Furthermore, sacroiliitis is present in 52% of patients with SAPHO.¹⁰⁴ Its classical dermatologic features include both severe acne and palmoplantar pustulosis. On both histopathologic and radiographic analysis, SAPHO initially can be indistinguishable from osteomyelitis. Radiographic lesions are typically seen in the sternoclavicular joints.

Because of its overlap with SpA, it has been suggested that SAPHO is not a unique entity but rather one component along a spectrum of disease.¹⁰⁵ Not only does it have clinical and radiographic features similar to those of SpA, but infection may also play a role in its pathogenesis. A review of the results of several smaller studies proposed a possible link between *Propionibacterium acnes* infection and SAPHO.¹⁰⁶ Sixty-nine patients underwent bone biopsy, and *P. acnes* was isolated from 24 specimens. Furthermore, intraarticular injection of inactivated *P. acnes* in the knees of laboratory rats can cause joint lesions, including bony erosions and proliferation of the synovial lining.¹⁰⁷ Also suggestive of an infectious cause is the observation that SAPHO may be responsive to antibiotics. In one case improvement in magnetic resonance imaging findings, decrease in skin disease activity, and improvement in osteitis occurred after completion of a 4-month course of azithromycin.¹⁰⁸ By three months after the completion of antibiotic treatment, however, the benefits had disappeared.

These findings raise the possibility that SAPHO is a reactive osteitis that mechanistically is along the same spectrum as ReA. We have previously proposed a classification system to address this issue.¹⁰⁹ If the traditional definition of ReA is used, SAPHO does not meet its diagnostic criteria, but there are several features which suggest that SAPHO has an infectious trigger and may be a variant of ReA (Fig. 112.8).

Clostridium difficile and Giardia lamblia

Classically, *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia* have been implicated as the pathogens responsible for the infections preceding ReA. However, there are a number of reported cases of *C. difficile*-associated ReA. In these cases knees and wrists are the most common sites of involvement. Although the temporal relationship is clear, *C. difficile* has not been isolated from the joint itself, and the infection is not associated with *C. difficile* bacteremia. A retrospective analysis in Canada demonstrated that the incidence of *C. difficile* infection had increased 4-fold from 1991 to 2003, with

Followup study on patients with Reiter's disease and reactive arthritis, with special reference to HLA-B27. Arthritis Rheum 1982;25:249-59.

Fig. 112.8 Proposed classification of spondyloarthritis. Note that SAPHO (synovitis, acne, pustulosis, hyperostosis, osteitis) is on a spectrum with reactive arthritis (ReA). AS, ankylosing spondylitis; EA, enteropathic arthritis; PsA, psoriatic arthritis; SA, SAPHO; USpA, undifferentiated spondyloarthritis. (From Rohekar G, Inman RD. *Conundrums in nosology: synovitis, acne, pustulosis, hyperostosis, and osteitis syndrome and spondylarthritis*. *Arthritis Rheum* 2006;55:665-9.)

a 10-fold increase in individuals older than 65 years.¹¹⁰ Given this marked increase in incidence, rheumatologists should expect to encounter an increasing number of patients with *C. difficile*-associated ReA. Perhaps with more clinical exposure a more uniform approach to treatment will evolve. In the 40 documented cases, a variety of treatment modalities were used; however, on average, cases resolved in 68 days with treatment of the underlying *C. difficile* colitis.¹¹¹

Like *C. difficile*, *Giardia* is a gastrointestinal pathogen that has been associated with ReA, albeit rarely. It is typically acquired by drinking water in rural areas. In a case series of patients with nonoutbreak *Giardia* infections it was demonstrated that 11.7% of patients experienced joint pain, most commonly affecting the knee, and 13.6% experienced ocular symptoms.¹¹² Although this study did not include sacroiliac involvement in the analysis, previous case reports have documented its occurrence.¹¹³

It is clear that atypical pathogens can lead to a clinical presentation consistent with ReA. For this reason, the traditional definition of ReA needs to be revisited to include these and other atypical pathogens that have yet to be identified.

Streptococcal infections

According to the current definition of ReA, only infections with pathogens that affect the gastrointestinal or genitourinary tract lead to a diagnosis of ReA. However, group A streptococci and *C. pneumoniae*, both implicated in respiratory tract infections, have been associated with ReA. Although *C. pneumoniae* is far less commonly linked to ReA, PCR analysis has recovered its DNA from synovial tissue of patients with ReA.¹¹⁴ Poststreptococcal ReA can present as a predominantly lower extremity oligoarthritis and may have an associated enthesitis or tendonitis.¹¹⁵ One review concluded that poststreptococcal ReA is a heterogeneous group of disorders, some of which share features of SpA and others of which are more like acute rheumatic fever (ARF).¹¹⁶ The consensus is that ARF and poststreptococcal ReA are distinct clinical entities. Poststreptococcal ReA is characterized by a longer interval between infection and symptom onset and does not respond as readily to salicylates. The pericardial disease and valvular heart disease characteristic of ARF are not recognized as a feature of poststreptococcal ReA.

TREATMENT

Triggering infection

All patients with acute *C. trachomatis* infection should receive the routine treatment (e.g., azithromycin 1 g as a single dose or a 7-day course of

doxycycline 200 mg/day, with partners treated as well). If a diarrheal episode associated with ReA is self-limited, it is not treated with antimicrobial agents.

Acute arthritis

The use of nonsteroidal antiinflammatory drugs (NSAIDs), often in a full dose, is usually of major benefit and should be first-line treatment for the acute arthritis. Intraarticular glucocorticoid injections are usually of benefit in patients with monoarticular or oligoarticular disease. Enthesitis may also respond to local corticosteroid injections. Systemic use of corticosteroids may be instituted if there is severe polyarthritis, if systemic inflammation is high, or if the patient is severely disabled. The starting dosage of prednisone is usually 20 to 40 mg/day.

Extraarticular symptoms

Acute anterior uveitis needs a prompt diagnosis and treatment with topical glucocorticoids and mydriatics. The outcome is usually good, but in about 5% of the patients the inflammation progresses to chronic uveitis. In severe cases, TNF-blocking agents have been used in uncontrolled fashion for the treatment of uveitis.

Skin and mucosal lesions

Keratoderma and pustular lesions mimic psoriasis and can be treated in the same way with topical glucocorticoids. In severe cases, methotrexate may be used and may have some benefit for more prolonged arthritis. Circinate balanitis and oral mucosal lesions usually respond to mild topical glucocorticoids.

Chlamydia-induced reactive arthritis

C. trachomatis represents the most common pathogen to trigger ReA, with 4% to 15% of infected individuals developing ReA. Recent studies have shown that both *C. trachomatis* and *C. pneumoniae* are able to disseminate from their site of primary infection to distant sites, such as synovium, and establish residence in the tissues. At these distant sites, the pathogens enter into a persistent yet aberrant state at which point the organisms are unable to be cultured; however, they are detectable by electron microscopy and nucleic acid detection methods. These features seem specific for CiReA, and it is noteworthy that in post-enteritis ReA, controlled studies examining the introduction of antibiotics during ongoing ReA have shown no effect on the course of the arthritis. In 2010 a clinical trial demonstrated that combination antibiotics could alter the course of CiReA.¹¹⁷ Patients were randomly assigned to receive placebo, doxycycline plus rifampin, or azithromycin plus rifampin. After 6 months of treatment, 63% of patients assigned to receive combination antibiotic therapy versus 20% of patients assigned to receive placebo experienced clinical improvement as measured by swollen joint count. Furthermore, 70% of patients who received antibiotics demonstrated clearance of *Chlamydia* as measured by PCR assay of peripheral blood mononuclear cells. Although several previous studies had used antibiotics in treating ReA, this is the first that demonstrated clinical improvement and examined clearance of *Chlamydia*. This trial was unique in that it enrolled only patients with blood or synovial tissue that tested positive for *Chlamydia* by PCR analysis. Other studies using antibiotics have enrolled patients with heterogeneous causes of ReA. Furthermore, they have often employed antibiotic monotherapy, which may not be effective in treating infections with aberrant pathogens. These findings lead to a reconsideration of the definition of ReA as a nonseptic arthritis (Table 112.3).

Disease-modifying antirheumatic drugs

Because about 50% of patients recover from ReA within the first 3 to 4 months, use of disease-modifying antirheumatic drugs (DMARDs) often is not considered. Sulfasalazine, if started during the first 3 months of ReA, may induce clinical remission more rapidly compared with placebo. Sulfasalazine or methotrexate may also be effective in chronic ReA when NSAID therapy has proved ineffective in controlling the arthritis or enthesitis, but there are few prospective trials to determine efficacy in this setting.

Biologic agents in the treatment of reactive arthritis

Traditionally the treatment of ReA involves an initial trial of NSAIDs and local corticosteroid injections with the addition of a DMARD should the individual continue to be symptomatic. As stated, limited evidence exists

TABLE 112.3

regarding the use of DMARDs, in part because of the relative infrequency of their use since approximately 50% of patients recover from ReA within the initial 6 months and only 4% to 19% of patients go on to develop a protracted ReA lasting longer than 1 year.¹¹⁸ Unlike the other clinical subsets of SpA, no guidelines exist for ReA with respect to more aggressive treatment should the initial therapy fail. Because there are no guidelines and most patients respond to NSAIDs, there are a limited number of reports of cases in which patients were given biologic agents.

There is limited experience with the use of anti-TNF agents in ReA (Table 112.4). In the largest reported experience with biologic therapy in ReA, the efficacy and safety of etanercept (25 mg subcutaneously twice weekly) was examined in 16 patients with ReA in a 6-month open-label trial.¹¹⁹ Synovial biopsies with PCR analysis of specimens were performed before and after treatment with etanercept. Ten of 16 patients completed the trial. Six patients withdrew, but none had a worsening of arthritis or infection. Of the 10 who completed the study, 9 could be classified as treatment responders, including 3 who showed evidence of bacterial organisms on PCR analysis before initiation of etanercept therapy; PCR results became negative in 2 patients while they were taking etanercept. Five of 6 patients in whom adequate synovial biopsy specimens were obtained showed improvement but not normalization of histologic findings.

The most recent study to examine the efficacy of anti-TNF agents in ReA was a retrospective analysis of data for 10 patients.¹²⁰ Ten patients with ReA previously refractory to treatment with NSAIDs and DMARDs received anti-TNF therapy at a median of 6 months (range, 2 to 12 months) from the

onset of ReA to the initiation of treatment. The median follow-up was 20.6 months. Anti-TNF therapy was rapidly effective in nine patients (90%), as shown by the swift effect on visual analogue scale pain score, tender joint count, swollen joint count, and extraarticular manifestations as well as the corticosteroid-sparing effect. The relatively short disease duration in this study raises the issues of generalizability and cost effectiveness. Given the self-limited nature of ReA in most cases, it is unclear whether the resolution of disease was secondary to the anti-TNF treatment or simply its spontaneous resolution. Understandably, there is a theoretical concern in administering an anti-TNF agent to someone who is harboring a potential pathogen, but in the studies conducted to date this does not seem to be an issue. In the study described earlier no adverse events, including severe infection, were documented.¹²⁰ Only mild infections were reported, none of which was associated with the triggering infection.

PROPHYLAXIS

There is no controlled evidence that chemotherapy initiated to treat urethritis can diminish the risk of recurrent ReA. Nevertheless, because a recurrent attack is often preceded by an infection, it is logical to tell patients how to prevent the potential triggering infections in the future. Avoidance of unprotected sex is sound advice with respect to *C. trachomatis* infection. When visiting regions where the risk of foodborne infections is high, the traveler should adopt caution in consumption of uncooked foods. Tap water and ice cubes should be considered contaminated. If the patient develops diarrhea, a fluoroquinolone (e.g., ciprofloxacin 750 mg as a single dose or 500 mg twice a day for 3 days) is effective for traveler's diarrhea and is also effective against most strains of *Salmonella*, *Shigella*, and *Yersinia*. In a patient with previous ReA, the treatment should be continued until the results of a stool culture are available. Fluoroquinolone resistance is an increasing problem in *Campylobacter* isolates from travelers returning from Asia, Africa, and Latin America.¹²⁶ Therefore, if there is a risk of *Campylobacter* infection (e.g., visit to a farm, consumption of poultry or egg-containing food), azithromycin (1 g as a single dose or 500 mg once daily for 3 days) is more preferable for traveler's diarrhea.¹²⁷ In rare cases, initial treatment with the combination of azithromycin and a fluoroquinolone may be considered to cover the major agents causing traveler's diarrhea, including fluoroquinolone-resistant *Campylobacter*. If the patient develops community-acquired pneumonia, treatment with the combination of a macrolide and a β -lactam drug covers both pneumococcal pneumonia and *C. pneumoniae* infection.

Preventing a recurrence of ReA is influenced more by advice than by antibiotic treatment. "Practice safe sex" is sound advice for all sexually active individuals. In patients with a history of ReA following a genitourinary tract infection, such advice should be reinforced. Similarly, patients who have had episodes of ReA following enteric infections should exercise extra precaution with regard to local food and hygiene when traveling to locales where enteric pathogens are common.

FUTURE DIRECTIONS IN REACTIVE ARTHRITIS

With the advent of improved methods of detecting pathogens in the synovium and the recognition of an expanding number of pathogens implicated in ReA, there remains a challenge to create a practical and more generalized definition of ReA. Presently, inclusion and exclusion criteria are not well defined, and clinicians are often left to treat ReA based on clinical experience. Current evidence suggests that ReA is a variant of septic arthritis in which the pathogen cannot be cultured. This should direct future research efforts toward therapies targeted at eradication of the intraarticular pathogens. But before such initiatives can be taken, more reliable methods for detecting these pathogens in the joints need to be developed. With increased use of biologic agents for the treatment of SpA, defined guidelines need to be formulated that balance both the risk and cost of these agents in the treatment of ReA.

SUMMARY: KEY ELEMENTS OF THE CLINICAL APPROACH TO REACTIVE ARTHRITIS¹²⁸

(Box 112.3)

Monoarthritis in a young adult should raise the possibility of ReA. ReA most often affects adults between 18 and 40 years of age and presents as a monoarthritis or oligoarthritis. The knee, ankle, or one of the metatarsophalangeal joints is usually affected first. Septic arthritis must be always be considered and excluded in any monoarthritis. Culture of

BOX 112.3 CLINICAL HIGHLIGHTS OF REACTIVE ARTHRITIS (ReA)

- In ReA, exposure to an infectious agent leads to the development of an inflammatory arthritis and other characteristic clinical findings.
- Approximately 50% of cases of ReA and undifferentiated oligoarthritis can be attributed to a specific pathogen by a combination of culture and serologic testing. The predominant organisms are *Chlamydia*, *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter* species.
- The frequency of ReA following exposure to potential etiologic agents is between 3% and 10%.
- ReA characteristically involves the joints of the lower extremities in an asymmetric, oligoarticular pattern. Dactylitis in the feet is typical of ReA.
- The presence of HLA-B27 increases disease susceptibility but is neither sufficient nor necessary for ReA to occur. Individuals who are HLA-B27+ tend to have more severe and longer episodes of ReA.
- Cutaneous manifestations of ReA include (1) oral ulcers, typically painless; (2) keratoderma blennorrhagicum, a papulosquamous rash on palms and soles; and (3) circinate balanitis, characterized by shallow ulcers on the penis.

synovial fluid is the only definitive method of differentiating septic arthritis from ReA.

Dysuria and a genital rash can follow infections of the gastrointestinal tract as well as the genitourinary tract. When genitourinary complaints occur concurrently with an inflammatory arthritis, clinicians may assume that a sexually transmitted disease has been the inciting event. However, genitourinary symptoms and signs are perfectly compatible with the syndrome of ReA that follows a gastrointestinal tract infection. A sexually transmitted disease need not be invoked to explain genitourinary features.

The enthesitis of ReA can be the dominant feature of the disease. Enthesitis, particularly Achilles tendonitis and plantar fasciitis, can be profoundly

disabling in the acute phase. Enthesitis overshadows inflammatory joint symptoms in some patients.

The uveitis of ReA is anterior, unilateral, and highly symptomatic. ReA is associated with an anterior uveitis that tends to affect one eye at a time. The finding of concurrent bilateral disease or disease in the posterior pole of the eye strongly suggests other diagnoses. Patients with the anterior uveitis of ReA have pronounced photophobia, eye pain, ocular erythema, and tearing. In addition to topical glucocorticoid eye drops, a mydriatic agent is essential to dilate the involved eye and prevent the formation of synechiae between the pupil and the lens.

Recurrence of ReA associated with sexually acquired infection is not uncommon. Approximately 50% of such patients experience subsequent episodes. In contrast, recurrence after enteric infection is uncommon. Patients should be advised about the risk that reinfection will lead to recurrence of arthritis and about specific precautions for avoiding reinfection. The precise role of repeated infections in precipitating recurrences of ReA is not clear. Additional genital tract infections have been associated with recurrent ReA, but reinfection with enteric bacteria—even the same species that caused the initial episode—does not always lead to a recurrence of ReA.

The interval between antecedent infection and ReA may extend to 4 weeks, although an interval of 1 to 2 weeks after the inciting infection is typical for the appearance of ReA. Patients with joint symptoms and other clinical features compatible with ReA therefore must be questioned closely about more remote occurrences of infection.

Postdiarrheal arthritis should always occasion a search for gastrointestinal pathogens as well as consideration of inflammatory bowel disease. The new onset of joint pain in the setting of diarrhea may indeed herald a case of inflammatory bowel disease with accompanying arthritis. However, infectious diarrhea caused by bacteria, parasites, or their toxins must be excluded definitively as the first priority. Examination of stool specimens for leukocytes, ova, and parasites as well as *C. difficile* toxin assays are critical in this evaluation.

SPONDYLOARTHRITIS

113

Classification and epidemiology of spondyloarthritis

■ MARTIN RUDWALEIT

- Ankylosing spondylitis (AS), reactive arthritis, undifferentiated spondyloarthritis, and arthritis associated with psoriasis or inflammatory bowel disease constitute spondyloarthritis (SpA), a group of interrelated inflammatory disorders with overlapping clinical manifestations and shared genetic markers.
- Clinical manifestations of the spondyloarthritides include axial manifestations such as inflammatory back pain and peripheral manifestations such as peripheral arthritis, enthesitis, dactylitis, and uveitis. HLA-B27 is the major contributing gene in SpA.
- The entire group of spondyloarthritides has a prevalence of 0.5% to 1.9%. AS, the largest subgroup, has a prevalence of 0.1% to 1.4%, which depends to some degree on the frequency of HLA-B27 in the population.
- Classification criteria were established for AS, for the entire group of spondyloarthritides, and recently for axial and for peripheral SpA.
- In the Assessment of SpondyloArthritis international Society classification criteria for axial SpA, sacroiliitis on magnetic resonance images is as important as sacroiliitis on radiographs, so that not only AS but also early axial SpA is captured.

CLASSIFICATION OF SPONDYLOARTHRITIS

The evolutionary concept of spondyloarthritis

Although anatomic and clinical descriptions of patients with advanced ankylosing spondylitis (AS) date back to the 16th century, it was not until the 1930s that the German radiologist Krebs reported that radiographic sacroiliitis is present in nearly all AS patients and that sacroiliitis occurs early in the course of the disease.¹ These findings were subsequently confirmed by Forestier in France and Scott in England, and formed the basis for the central role of radiographic sacroiliitis in criteria for AS. The Rome criteria² formulated in 1961 were the first set of criteria developed to classify AS. Modifications led to the New York criteria³ and eventually to the modified New York criteria for AS in 1984.⁴ Accordingly, a patient can be classified as having definite AS if one clinical criterion plus the radiologic criterion (radiographic sacroiliitis grade 2 or higher bilaterally or grade 3 or higher unilaterally) are fulfilled (Table 113.1). The modified New York criteria are the most widely used criteria for both classification and diagnosis of AS. However, it takes on average 6 to 8 years from the onset of inflammatory back pain until a definite diagnosis of AS is made because of the relatively late appearance of definite radiographic sacroiliitis on plain radiographs,⁵ a requirement of the modified New York criteria.

In the 1970s, Moll and Wright established the concept of a group of interrelated disorders termed *seronegative spondyloarthritides* that initially included AS, psoriatic arthritis, reactive arthritis, arthritis with ulcerative

colitis or Crohn disease, Whipple disease, and Behçet syndrome.⁶ These disorders were termed *seronegative* because patients with these conditions typically tested negative for rheumatoid factor. These conditions were considered interrelated because of the absence of subcutaneous nodules (as found in rheumatoid arthritis); the presence of similar clinical manifestations such as involvement of the sacroiliac joints and spine as well as peripheral joints and skin and mucosal involvement; and a presumed similar genetic background. The discovery in 1973 of the strong association of human leukocyte antigen B27 (HLA-B27) with AS and, to a lesser extent, with other spondyloarthritis (SpA) subgroups strongly supported this concept. As a result of subsequent research findings, including the lack of a genetic association of HLA-B27 with Behçet syndrome and identification of *Tropheryma whippelii* as the causative microbe in Whipple disease, both Behçet syndrome and Whipple disease were excluded from the spondyloarthritides.

In the 1990s the Amor criteria⁷ and the European Spondylarthropathy Study Group (ESSG) classification criteria⁸ were established as classification criteria for the entire group of spondyloarthritides (Table 113.2). The Amor and ESSG criteria took into consideration the fact that some patients have clinical features typical of SpA but cannot be assigned to any one of the specified SpA subgroups (i.e., AS, psoriatic arthritis, reactive arthritis, and arthritis with ulcerative colitis or Crohn disease). This subgroup of patients with so-called undifferentiated SpA became part of the SpA concept and were then classifiable by either set of criteria. Moreover, both the Amor and ESSG criteria underlined the typical characteristics of peripheral arthritis in SpA, which often is asymmetric, oligoarticular, and involves the lower extremity. Although in the 1980s and 1990s the term *spondyloarthropathy* was used, François and colleagues proposed in the mid-1990s that the term *spondyloarthritis* be adopted instead, based on pathologic findings.⁹ The term *spondyloarthritis* underlines the inflammatory nature of these conditions more strongly than does the term *spondyloarthropathy* and is therefore preferred.

Diagnosis and classification of axial spondyloarthritis

The introduction of magnetic resonance imaging (MRI) has revolutionized the imaging of patients with sacroiliitis and has led to new criteria for the diagnosis and classification of SpA. By the use of MRI, acute inflammation of the sacroiliac joints with or without signs of structural damage can be accurately visualized. Active sacroiliitis on MRI has been shown to predict the later appearance of sacroiliitis on radiographs,^{10,11} which adds validity to the finding of inflammation on MRI in early disease. Thus a patient at an early stage of AS typically has clinical symptoms suggestive of AS, such as inflammatory back pain, but may not show sacroiliitis on radiographs.³ In such a patient sacroiliitis may be reliably detectable on MRI, which facilitates earlier diagnosis. Since definite structural damage is not yet visible on radiographs at this stage, it has been proposed that this disease stage be referred to as *nonradiographic axial SpA* (nr-axSpA) rather than *early AS*

(Fig. 113.1).¹² Thus axial SpA encompasses AS and nr-axSpA, and the evolution from nr-axSpA to AS depends on time and on disease severity factors. The concept of axial spondyloarthritis (axSpA) also implies that not all patients will progress to AS. The precise proportion of patients with nr-axSpA who experience disease progression is currently unknown, as are the factors determining the rate of progression. Male gender, the extent of inflammation on MRI, disease duration, and other still-unknown factors play a role. Attempts have been made to provide some guidance on how to establish a diagnosis of nr-axSpA. These include a diagnostic algorithm¹³ as well as a probability approach based on likelihood ratios.¹² Of importance, a combination of typical SpA symptoms and findings is necessary to arrive at a diagnosis. Age at onset in axSpA is usually during the third decade of life. Back pain is the leading symptom, and many but not all patients have the symptom of inflammatory back pain, for which several definitions are available (Table 113.3).¹⁴⁻¹⁶ However, inflammatory back pain alone does not

suffice for making a diagnosis of axSpA because of the low specificity of the symptom (75% to 80%) and the fact that axSpA accounts for no more than 5% of cases of chronic low back pain. The presence of inflammatory back pain alone results in an estimated likelihood of the presence of axSpA of around 16%, regardless of which set of criteria for inflammatory back pain¹⁴⁻¹⁶ is used (see Table 113.3). Rather, a combination of clinical, laboratory (HLA-B27), and imaging (MRI) findings is necessary to arrive at a high enough disease probability.^{12,13} Some patients with nr-axSpA have high disease activity (signs and symptoms) comparable to that of patients with established AS¹⁷ and require effective treatments, including nonsteroidal antiinflammatory drugs and anti-tumor necrosis factor agents, just as do patients with established AS. To better standardize the conduct of clinical trials in patients with nr-axSpA, the Assessment of SpondyloArthritis international Society (ASAS) has developed and validated new classification criteria for axSpA.^{18,19} According to the ASAS classification criteria for axSpA, a patient with chronic back pain and age at onset of less than 45 years can be classified as having axSpA if sacroiliitis is apparent on imaging (radiographs or MRI scans) plus at least one additional SpA feature is present, or, in the absence of sacroiliitis on imaging, if HLA-B27 positivity plus at least two additional SpA features are present (Fig. 113.2). Thus sacroiliitis on MRI scans has been given as much weight as sacroiliitis on radiographs. A preliminary definition of sacroiliitis on MRI scans has also been elaborated based on consensus and will be refined as necessary.²⁰ The new ASAS classification criteria encompass the entire spectrum of SpA patients with predominantly axial manifestations, from nr-axSpA to AS. Of note, the new ASAS classification criteria are intended to be used as classification criteria for clinical trials and are not intended to be used as diagnostic criteria.

Classification of peripheral spondyloarthritis

For peripheral SpA, both the Amor⁷ and ESSG criteria⁸ have been used in the past. New classification criteria for predominantly peripheral SpA were also developed by the ASAS.²¹ The peripheral SpA criteria focus on peripheral arthritis of the SpA type, enthesitis, or dactylitis as entry criterion and are fulfilled if in addition either one or two other SpA features are present (Fig. 113.3). In the original study the new ASAS criteria showed a

TABLE 113.1
Modified New York Criteria for ankylosing spondylitis

Clinical criteria:
1. Low back pain and stiffness for > 3 mo that improves with exercise but is not relieved with rest
2. Limitation of motion of the lumbar spine in both the sagittal and frontal planes
3. Limitation of chest expansion relative to normal values corrected for age and sex
Radiologic criterion:
Sacroiliitis grade ≥ 2 bilaterally or grade 3-4 unilaterally
Definite ankylosing spondylitis:
■ The radiologic criterion is associated with at least one clinical criterion.
From van der Linden S, Valkenburg HA, Cats A. Evaluation of diagnostic criteria for ankylosing spondylitis. A proposal for modification of the New York criteria. <i>Arthritis Rheum</i> 1984;27:361-8.

TABLE 113.2
Criteria for spondyloarthritis (SpA)

Amor criteria ⁷	ESSG criteria ⁸
A. Past or current clinical manifestations	Inflammatory back pain or synovitis
1. Back pain at night and/or back stiffness in the morning (1 point)	■ Asymmetric or
2. Asymmetric oligoarthritis (2 points)	■ Predominantly lower limb
3. Gluteal pain without other details (1 point) or alternating gluteal pain (2 points)	AND
4. Sausage-like digit or toe (2 points)	One or more of the following:
5. Heel pain or other enthesopathy (2 points)	■ Positive family history
6. Iritis (2 points)	■ Psoriasis
7. Nongonococcal urethritis within 1 mo before the onset of arthritis (1 point)	■ Inflammatory bowel disease
8. Acute diarrhea within 1 mo before the onset of arthritis (1 point)	■ Urethritis, cervicitis, or acute diarrhea within 1 mo before arthritis
9. Past or current psoriasis and/or balanitis and/or inflammatory bowel disease (2 points)	■ Buttock pain alternating between right and left gluteal areas
B. Radiographic changes	■ Enthesopathy
10. Sacroiliitis grade 2 or more if bilateral, grade 3 or more if unilateral (3 points)	■ Sacroiliitis (radiography)
C. Predisposing genetic factors	
11. Presence of HLA-B27 antigen and/or family history of ankylosing spondylitis, Reiter syndrome, psoriasis, uveitis, or chronic bowel disease (2 points)	
D. Responsiveness to treatment	
12. Improvement within 48 hours after initiation of a nonsteroidal antiinflammatory drug and/or recurrence within 48 hours after discontinuation of a nonsteroidal antiinflammatory drug (2 points)	
Definite SpA if ≥6 points, probable SpA if 5 points.	
ESSG, European Spondylarthropathy Study Group.	

Fig. 113.1 The concept of axial spondyloarthritis (SpA) comprises nonradiographic axial SpA and ankylosing spondylitis. Note that all patients with AS start as nonradiographic axial SpA but not all patients with nonradiographic axial SpA progress to ankylosing spondylitis. MRI, magnetic resonance imaging. Criteria for inflammatory back pain (IBP)

Calin criteria ¹⁴	Berlin criteria ¹⁵	IBP according to ASAS experts ¹⁶
Age at onset < 40 yr Duration of back pain > 3 mo Insidious onset Morning stiffness Improvement with exercise (at least four of five present)	Morning stiffness > 30 min Improvement with exercise, not with rest Awakening at second half of the night because of pain Alternating buttock pain (at least two of four present)	Age at onset < 40 yr Insidious onset Improvement with exercise No improvement with rest Pain at night (with improvement on rising) (at least four of five present)

ASAS, Assessment of SpondyloArthritis international Society.

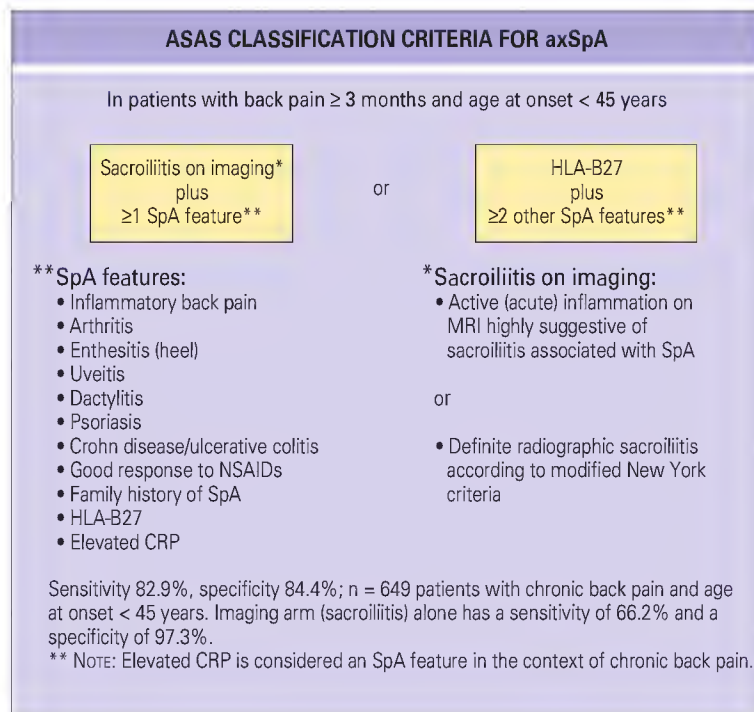

Fig. 113.2 Assessment of SpondyloArthritis international Society (ASAS) endorsed criteria for classifying patients with axial spondyloarthritis (SpA). To be applied in patients with a diagnosis of axial SpA, age at onset less than 45 years and chronic back pain. Patients can be classified either by the imaging arm with sacroiliitis on radiographs or MRI, plus at least one further SpA feature, or by the clinical arm with positivity for HLA-B27 plus at least 2 further SpA features. CRP, C-reactive protein; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal antiinflammatory drugs. (Modified with permission from Rudwaleit M, van der Heijde D, Landewé R, et al. The development of Assessment of SpondyloArthritis international Society classification criteria for axial spondyloarthritis (part II): validation and final selection. *Ann Rheum Dis* 2009;68:777-83.)

Fig. 113.3 Assessment of SpondyloArthritis international Society (ASAS) endorsed criteria for classifying peripheral spondyloarthritis (SpA). Patients have either peripheral arthritis, enthesitis, or dactylitis with at least one of SpA features shown in the left box or at least two SpA features shown in the right box. IBP, inflammatory back pain; MRI, magnetic resonance imaging. (Modified with permission from Rudwaleit M, van der Heijde D, Landewé R, et al. The Assessment of SpondyloArthritis international Society classification criteria for peripheral spondyloarthritis and for spondyloarthritis in general. *Ann Rheum Dis* 2011;70:25-31.)

good balance between sensitivity and specificity and performed better than the Amor and ESSG criteria, particularly with regard to sensitivity, which implies better performance in early disease. Although results from a first validation study²² are clearly promising, further studies in other settings are warranted.

PREVALENCE OF SPONDYLOARTHRITIS

The prevalence of AS has been reported from population studies to vary between 0.1% in the Netherlands and 1.1% to 1.4% in Norway.^{23,24} A blood donor study in Germany estimated a prevalence of AS of 0.55%, taking into account the male-female ratio in AS of 2:1 to 3:1.^{25,26} The incidence of AS

has been reported to be approximately 7.2 per 100,000 adults in the United States, 6.9 per 100,000 adults in Finland, and 7.26 per 100,000 in Norway and appears to have been stable over the past 50 years.²⁷ The incidence and prevalence of AS generally mirror to some extent the frequency of HLA-B27 in the population, which explains the virtual absence of AS in southern Africa, low rates of AS in Japan, higher rates in Norway than in other European countries, and very high rates among the native peoples of the circumpolar arctic and subarctic regions of Eurasia and North America.²⁷ The risk of development of AS in healthy HLA-B27+ subjects has been studied in North America, European countries including Scandinavia, Siberia, and Asia and has been reported to be approximately 6% in various populations (range, 1% to 8%).^{23,24,27} Estimates of the prevalence of the entire group of spondyloarthritides in North America, Germany, France, Greece, and Lithuania range from 0.3% to 1.9%, and therefore are as high as those reported for rheumatoid arthritis.²³⁻³⁰ Again, higher prevalence rates of 2.5% for the entire group of spondyloarthritides have been reported for Alaskan Eskimos.³¹ Within the group of spondyloarthritides it appears that AS and undifferentiated SpA are the two most common subgroups.²⁵

GENETIC FACTORS

The precise etiopathogenesis of AS is still unknown despite extensive research. The role of genes is undisputable, however, because AS has been long known to be highly familial. A family history of AS or other SpA is reported by 7% to 36% of AS patients.¹³ In first-degree relatives of AS patients the risk of developing AS is around 10%. The risk increases to 20% if the relative is HLA-B27+ but decreases to less than 1% if the relative is HLA-B27-.²³ Twin studies have revealed a high degree of heritability with concordance rates of 63% among monozygotic twins and 12% among dizygotic twins, the latter increasing to 23% if both twins are HLA-B27+. From these family studies it has been estimated that more than 90% of the risk of developing AS is genetically determined.³² The strong association of HLA-B27 has been known for more than 40 years; HLA-B27 is found in 80% to 95% of AS patients compared with 6% to 9% of the general populations of Central Europe and North America. Yet the molecular mechanism underlying the strong association between HLA-B27 and AS has not been elucidated. Many of the more common HLA-B27 subtypes such as B*2705, B*2704, and B*2702 are strongly associated with AS. However, two subtypes are less strongly associated with AS: HLA-B*2706, which occurs commonly in Southeast Asia, and HLA-B*2709, which can be found in Sardinia. Again, the mechanism behind this differential association is unclear but may relate to peptide binding and/or recognition characteristics. HLA-B27 is associated with a younger age at onset¹⁷ and predisposes to axial involvement in SpA because the frequency of HLA-B27 is highest in AS, whereas in peripheral SpA, such as reactive arthritis or undifferentiated SpA, the frequency of HLA-B27 ranges from 20% to 70%. In addition to HLA-B27 two other major AS-related genes have been recently identified and replicated: those for the

interleukin-23 receptor and endoplasmic reticulum aminopeptidase-1 (ERAP1), formerly known as *type 1 tumor necrosis factor receptor-shedding aminopeptidase regulator-1* (ARTS1). Both genes are of great pathophysiologic interest because they encode proteins involved in inflammatory pathways and/or peptide presentation.^{33,34} Of note, ERAP1 appears to be involved in peptide handling in a HLA-B27 dependent fashion.³⁵

IMPACT OF GENDER

Previously, AS was considered a predominantly male disease with a male-female ratio of 9:1. In more recent studies, this ratio has been found to be 2:1 to 3:1, which may be due to higher awareness of the occurrence of the disease in females and better access to diagnostic tests in general. Large epidemiologic studies revealed that females with AS are slightly younger at disease onset by 1 to 2 years, on average, but are diagnosed later than males, again on average, by 1 to 2 years.³⁶⁻³⁸ Moreover, females with AS have, on average, less ankylosis of the spine as assessed by radiography in long-term follow-up studies and therefore less damage.^{36,39,40} It is thus assumed that females with AS on average have a milder form of the disease than their male counterparts.

In epidemiologic studies of undifferentiated SpA/nr-axSpA a male-female ratio of 1:1 is usually found,^{17,41,42} which obviously contrasts with the male-female ratio of 2:1 to 3:1 in AS. These findings suggest that male gender predisposes to structural damage, including ankylosis of the sacroiliac joints and spine as detected by radiography. This view is supported by recent data from an inception cohort of patients with axSpA, including patients with nr-axSpA and patients with AS, which clearly showed that male gender was significantly associated with the presence of radiographic sacroiliitis.¹⁷ Along this line, an earlier study in Alaskan Eskimos with SpA revealed that males were more likely to have ankylosis of the sacroiliac joints and advanced spinal mobility restrictions.³⁸ Clearly, more research is needed to study the role of gender and other factors for progression from nr-axSpA to AS in axSpA.

CONCLUSION

In various populations the entire group of spondyloarthritides occurs in 0.3% to 1.9% of the population and is as frequent as rheumatoid arthritis. Genes, in particular HLA-B27, have an important role in SpA. The presence of HLA-B27 is associated with an early age at onset and involvement of the axial skeleton. Great advances have been made in better characterizing the early stage of AS. The term *axial spondyloarthritis* is meant to function as an umbrella for all SpA with predominantly involvement of the axial skeleton, independent of the presence of structural damage on radiographs. The new ASAS classification criteria for axSpA are applicable not only to patients with AS but also to patients with active sacroiliitis on MRI without definite structural damage, which facilitates studies and clinical trials in early axSpA.

Clinical features of axial spondyloarthritis

■ LIANNE S. GENSLER

- Axial spondyloarthritis is a chronic systemic inflammatory rheumatic disorder with a predilection for axial skeletal involvement and inflammation at sites of bony insertions of tendons and ligaments (enthesitis).
- Sacroiliitis is the hallmark of the disease. There is a strong genetic predisposition associated with HLA-B27.
- Clinical manifestations include chronic inflammatory low back pain and stiffness as well as limitation of spinal mobility and chest expansion. Acute anterior uveitis or other less common extraarticular manifestations occur in some patients.
- There is an association with psoriasis, chronic inflammatory bowel disease, and reactive arthritis in some patients.
- Radiographic findings are characteristic of the disease, though this can take years to show up.
- Generally there is good symptomatic response to antiinflammatory doses of nonsteroidal antiinflammatory drugs.

INTRODUCTION

Ankylosing spondylitis (AS), perhaps the best known and characterized of the spondyloarthritis (SpA) family, is a chronic inflammatory disease affecting the axial skeleton, the entheses, and occasionally the peripheral joints. The hallmark of AS is inflammatory back pain (see later) associated with radiographic sacroiliitis and often spondylitis. In addition to the axial, enthesal, and appendicular skeletal involvement, AS can also be associated with extraarticular manifestations, especially uveitis and, less commonly, cardiac, pulmonary, and renal disease. AS can occur as a primary disorder or can complicate other types of SpA, especially in the setting of psoriasis and inflammatory bowel disease (IBD). A broader term, *axial spondyloarthritis*, has been adopted to describe all forms of SpA that affect the axial joints. This includes not only AS that meets the 1984 modified New York criteria¹ but also nonradiographic disease.²

CLINICAL FEATURES

Inflammatory back pain

The first symptoms of AS usually appear in adolescence to early adulthood and almost invariably start before the age of 45.³⁻⁶ The most characteristic presentation is that of inflammatory back pain, which accounts for about 15% of all types of chronic low back pain (Table 114.1).⁷⁻¹⁰ This is dull chronic low back pain (lasting longer than 3 months), insidious in onset, usually in the buttocks (or hips, as interpreted by the patient). It is worse in the early part of the morning, when it is associated with morning stiffness lasting at least 30 minutes; is relieved with exercise or activity (i.e., limbering up) and/or a hot shower; is worsened by rest; and usually is improved by the use of nonsteroidal antiinflammatory drugs (NSAIDs).⁸ In fact, a good response of back pain to NSAIDs within 48 hours is a good predictor of the presence of inflammatory low back pain and of axial SpA, with a sensitivity of 75%.^{5,11} Although the pain may be unilateral or intermittent at first (in

fact, alternating buttock pain is a cardinal feature of the disease), it usually becomes persistent and bilateral in the lower lumbar area.⁷⁻¹⁰

Occasionally, the first symptom comes from extraarticular sources, such as acute anterior uveitis or enthesitis; in fact, with disease onset in childhood, peripheral joint and enthesal manifestations figure prominently.²⁻⁵ Bone tenderness, especially over enthesal points (e.g., Achilles tendon insertion into the calcaneus), may also be a complaint in some AS patients.² Neck pain and stiffness is characteristic of advanced disease, although it can be a dominant feature in early AS in women.² In later disease, these gender differences in cervical spine involvement do not appear to be maintained.¹¹

Hip and shoulder involvement

The shoulders and hips are considered axial joints, and their involvement occurs in up to 50% of patients and is more common than involvement of the peripheral joints.²⁻⁴ In the hips, there may be progressive flexion deformity and eventual destruction of the joint.¹² Destructive changes in the hips are slowly progressive and are associated with marked deformity of the femoral head before the development of ankylosis. More commonly, however, nondestructive symmetric loss of the hip joint space is associated with a fairly characteristic osteophytic collar that forms at the junction of the femoral head and the neck.¹² Hip disease in AS is a marker of more severe disease in adults.¹³ There is a higher prevalence of hip involvement and greater need for hip arthroplasty in juvenile-onset AS.¹⁴ In the shoulders, joint space narrowing and erosive changes in the superolateral aspect of the humeral head, with eventual ankylosis, can occur. Chronic rotator cuff tears can also be seen in AS patients.¹⁵

Peripheral arthritis

Peripheral arthritis in joints other than the hips and shoulders is less common in AS, but when it occurs, it is usually an asymmetric oligoarthritis presenting predominantly in the lower extremities.¹⁶ When it develops early in the disease course, it is a predictor of more aggressive disease.¹⁶ It appears to be more common in women¹¹ and juvenile-onset AS.¹⁴

Chest wall involvement

With involvement of the thoracic spine (including costovertebral joints) and occurrence of enthesopathy at the costosternal and manubriosternal joints, patients may experience chest pain especially on coughing or sneezing, which sometimes is characterized as “pleuritic.”³⁻⁵ Occasionally, chest pain may be the presenting symptom of AS. Subsequently the costovertebral joints may fuse, which diminishes chest expansion and can lead to restrictive lung disease of a mechanical nature.

Enthesitis

The enthesitis is the insertion of a tendon, ligament, capsule, or fascia into bone. Enthesitis is inflammation of the origin and insertion of ligaments, tendons, aponeuroses, annulus fibrosis, or joint capsules and is a characteristic feature of SpA.²⁻⁶ Inflammation may occur at any enthesitis in AS, although it is most common in the entheses of the lower limbs, especially in the calcaneus at the insertion of the Achilles tendon and the plantar fascia. Pathologic examination of enthesitis in AS demonstrates local inflammation, fibrosis, erosion, and ossification.¹⁷⁻¹⁹ Bursitis and synovitis may also occur adjacent to the entheses, and it has been postulated that the entheses may be the initial site of joint inflammation in AS.¹⁷⁻¹⁹

TABLE 114.1
Differentiation of inflammatory versus mechanical low back pain (LBP)

	Inflammatory LBP	Mechanical LBP
Age of onset	<40 yr	Any age (usually later)
Type of onset	Insidious	Acute
Symptom duration	>3 mo	<4 wk
Morning stiffness	≥30 min	<30 min
Nocturnal pain	Common	Absent
Effect of exercise	Improvement	Exacerbation
Sacroiliac joint tenderness	Frequent	Absent
Back mobility	Loss in all planes (late finding)	Abnormal flexion
Chest expansion	Often decreased	Normal
Neurologic deficits	Unusual	Possible

Physical examination findings

The main finding on physical examination in patients with AS is loss of spinal mobility; however, this can be a late finding.² Limitation of flexion and extension of the lumbar spine as well as chest expansion is seen. Sacroiliac joint pain can also be elicited with direct pressure or movement and may be elicited in the acute phase of the disease; however, this finding lacks sensitivity.² Peripheral joint or enthesal inflammation can also be observed. Lumbar lordosis may be lost, atrophy of the buttocks can be present, exaggerated kyphosis may be observed, and the neck may stoop forward.² Resulting flexion contractures of the hips and knees may occur, with significant morbidity and disability.^{2,4} Mild to moderate reduction of chest expansion is often detectable in an early stage of AS.^{2,4}

Three physical measurements have been validated and recommended by the Assessment of SpondyloArthritis international Society (ASAS) as useful for evaluating patients with AS specifically and those with inflammatory back pain in general.²⁰⁻²² A modification of the Schober test is measured as the increase in distance upon maximal forward spinal flexion with extended knees of a 10-cm segment drawn on the patient's back with the inferior mark at the level of the superior aspect of the dimples of Venus. The measured distance should increase from 10 cm to at least 13.5 cm in an adult; however, this value has been recently brought into question in at least two studies suggesting that the normal reference range is actually lower (see Fig. 118.4d).^{23,24} Chest wall expansion with inspiration is measured with a tape measure placed circumferentially around the chest wall at the 4th intercostal space in men or the xiphisternum in women. Normal chest expansion in an adult has been reported to be more than 5 cm, although this may vary with age and gender. A more recent population-based study suggests lower normative values.²³ To measure the occiput-to-wall distance (a measure of kyphosis), the patient stands with heels and buttocks touching the wall behind and with the knees straight. The patient is asked how far back he or she can move the head while keeping the chin in the normal, tucked position. The distance between the posterior convexity of the occiput and the wall is measured to the nearest 0.1 cm. The better of two attempts is recorded. Any value greater than zero is regarded as abnormal. This does not appear to be true in patients older than age 50.²³ Tragus-to-wall distance is also a measure of kyphosis and is used as part of the composite Bath Ankylosing Spondylitis Metrology Index (BASMI) but is problematic because there is variation in tragus location across individuals.

Another measure that is used more and more commonly is the degree of lumbar lateral bending. Here the patient stands with the heels and back against the wall. There is no flexion of the knees nor bending forward. The distance between the patient's middle fingertip and the floor is measured. The patient then bends sideways, keeping the back against the wall without bending the knees or lifting the heels. A second reading is taken and the difference between the two is recorded. The best of two tries is recorded for left and right. The mean of left and right values gives the final result (in centimeters to the nearest 0.1 cm). Normal value is more than 10 cm.

Extraarticular manifestations
Uveitis

The anterior portion of the uvea consists of the iris and ciliary body, whereas the posterior portion is known as the *choroid*. Inflammation of the anterior

TABLE 114.2
Comparison of ankylosing spondylitis and related disorders

Feature	Ankylosing spondylitis	Psoriatic arthritis	Reactive arthritis	Enteropathic arthropathy
Gender (male:female)	2-3:1	1:1	1:1	1:1
Age of onset	<40 yr	35-55 yr	20-40 yr	Any age
Sacroiliitis or spondylitis	100%	~20%	~40%	<20%
Symmetry of sacroiliitis	Symmetric	Asymmetric	Asymmetric	Symmetric
Peripheral arthritis	~25%	95%	90%	5%-20%
Distribution	Axial and lower limbs	Variable	Lower limbs	Variable
HLA-B27 positivity	85%-95%	25%-60%*	30%-70%	7%-70%†
Uveitis	0%-40%	~20%	~50%	<15%

*60% when spondylitis present.
†70% when spondylitis present.

uveal tract is known as *anterior uveitis* or *iritis*. When the adjacent ciliary body is also inflamed, the process is known as *iridocyclitis*. Acute anterior uveitis (AAU) is the typical uveitis associated with AS.

AAU occurs in about 30% to 40% of patients with AS,²⁵⁻³⁰ of whom approximately 90% are HLA-B27 positive. Of patients with recurrent unilateral AAU, 50% are HLA B27 positive and most of these have some form of SpA (Table 114.2).²⁵⁻³⁰ Typically, AAU presents unilaterally with sudden onset and may be recurrent. Symptoms may include redness, pain, blurred vision, increased lacrimation, photophobia, and miosis. The diagnosis is characteristically confirmed by slit-lamp examination, which is also useful in monitoring response to treatment.

Prognosis is favorable in AAU, with resolution of symptoms within a few weeks. If treatment is delayed or inadequate, however, complications can occur; these include anterior synechiae (adherence of the iris to the cornea) and posterior synechiae (adherence of the iris to the lens), which can lead to cataracts and cystoid macular edema.^{29,30} Increased intraocular pressure can be seen. Macular edema has been shown to be the main factor that determines visual outcome in cases of uveitis.^{29,30} Although AAU is the most common uveitis associated with AS, posterior uveitis has been reported and tends to be more severe, especially in those with coexistent IBD.³⁰

Gastrointestinal manifestations

Up to 50% of patients with AS have both macroscopic and microscopic ileal and cecal inflammation seen on ileocolonoscopy.^{31,32} Moreover, two thirds of patients with undifferentiated SpA have histologically determined gut inflammation. Gut inflammation in AS appears to be immunologically related to that seen in Crohn disease. Those with chronic inflammatory lesions tend to have more severe erosive peripheral and hip arthritis.³³ Risk factors for evolution to overt IBD include the presence of chronic inflammatory gut lesions, persistence of elevated levels of inflammatory serum markers, and absence of HLA-B27 in the presence of sacroiliitis.³³ Patients with established IBD can have asymptomatic sacroiliitis, and HLA-B27 status has less predictive value in this group of patients.³²

Cardiac manifestations

The classic cardiac abnormalities in AS are aortitis, aortic regurgitation (AR), and conduction abnormalities (especially first-degree atrioventricular block).³⁴⁻³⁸ HLA-B27 appears to be an important genetic risk factor for cardiac conditions.³⁵ AR is well characterized and distinguished from aortic valvular dysfunction in other disorders.³⁵ Three factors contribute to the development of incompetent aortic valves: dilation of the aortic root, fibrotic thickening and downward retraction of the bases of the cusps, and inward rolling of the edges or margins of the cusps.³⁵ AR is present in 2% to 10% of patients with AS and increases in likelihood with longer disease duration.

Cardiac conduction abnormalities, including atrioventricular and intra-ventricular blocks, have been regarded as the most common cardiac complication in patients with AS.³⁵ Complete heart block has been found in 1%

to 9% of patients with AS.³⁵ Electrophysiologic studies show that the preferential level of block is in the atrioventricular node itself, in contrast with most cases of acquired complete heart block, in which 80% are within or below the bundle of His.³⁵

More common in AS is ischemic heart disease, peripheral vascular disease, and congestive heart failure with prevalence ratios of 1.2, 1.6, and 1.8, respectively, compared with control subjects matched for age, gender, and geographic location.³⁷ In a population study, both cerebrovascular and cardiovascular events were more common in AS. The excess risk was attributable to the younger AS patients.³⁸

Pulmonary manifestations

Involvement of the lung parenchyma is a well-recognized manifestation of AS.³⁹⁻⁴² The reported prevalence of pleuropulmonary involvement in AS is variable depending on the technique used to assess it. It is rare when assessed by plain radiography (1% to 2% of cases) but common when assessed by high-resolution computed tomography (HRCT).³⁹⁻⁴² The most frequently recognized manifestations are upper lobe fibrosis, mycetoma formation, and pleural thickening. Fusion of the costovertebral joints caused by inflammation and ankylosis of the thoracic spine can lead to restrictive ventilatory impairment on pulmonary function testing.⁴²

Pulmonary abnormalities on chest radiography consist mainly of irregular linear or reticulonodular opacities and cyst formation. The upper lobe fibrosis tends to be progressive. Another common finding is the presence of bilateral symmetric apical pleural thickening. The most common findings described on HRCT are linear opacities and bronchial wall thickening. The clinical implications of these observations remain unclear because lung involvement in AS is usually asymptomatic. Cigarette smoking in the setting of pulmonary fibrosis may increase the risk of spontaneous pneumothorax in AS.⁴³ There appears to be a higher prevalence of obstructive sleep apnea in AS patients compared with the general population.⁴⁴

Renal manifestations

Renal involvement in AS may include secondary amyloidosis (AA type), NSAID nephropathy, and glomerulonephritis.⁴⁵⁻⁴⁷ Renal amyloidosis is the most common cause of renal involvement in AS, occurring in 4% to 9% of AS patients; it is usually a complication of long-standing untreated disease and is associated with peripheral joint involvement, elevated erythrocyte sedimentation rate (ESR), and hypergammaglobulinemia.⁴⁶ Immunoglobulin A (IgA) nephropathy has been well described, although its true prevalence is unknown.⁴⁵⁻⁴⁷ It has been suggested that IgA nephropathy in AS patients is part of the disease spectrum and may indicate a common pathogenic mechanism.^{45,46} NSAID nephrotoxicity may result in interstitial nephritis with nephrotic-range proteinuria and/or acute renal failure.^{45,46} These manifestations usually occur in older individuals after long-term NSAID therapy and seem to be reversible with discontinuation of the NSAID.⁴⁶

Osteoporosis

Measurement of bone mineral density (BMD) in patients with spondylitis is complicated by false increases in spinal BMD from ossification, which has led some to recommend the use of quantitative computed tomography over standard dual energy x-ray absorptiometry (DEXA) for BMD measurements in AS patients. Others have suggested that lateral and volumetric DEXA may be more sensitive.⁴⁸ Nevertheless, up to half of patients with long-standing AS have been reported to have low BMD or osteoporosis.^{49,50} Decreases in BMD can be seen not only in the spine but also in the femoral neck by DEXA (which may be a more reliable measure).⁴⁹⁻⁵² It has been noted that osteoporosis is related to disease activity as measured by ESR, C-reactive protein (CRP) level, and BASDAI.⁵⁰ It has also been associated with older age, longer disease duration, limited metrology, and low body mass index.⁴⁹ Even in studies of disease of short duration (less than 10 years), low BMD is prevalent.⁵² The cause of osteoporosis in AS is still not completely understood, although treatment factors and decreased mobility or physical activity may lead to its development.⁴⁹ Histologic examinations point to an osteoclast-osteoblast imbalance.⁵⁰ It has also been shown that the vitamin D receptor gene may be involved in BMD differences, bone metabolism, and inflammatory processes in AS.⁵⁰

Spondylodiskitis and spinal fractures

An uncommon but well-recognized complication of AS is spondylodiskitis, a destructive diskovertebral lesion also called *Andersson lesion*. Typically, these lesions are more common in the thoracic and lumbar spine, sometimes with multilevel involvement⁵³⁻⁵⁵; however, cervical spondylodiskitis has been reported.⁵⁶ Pain and tenderness localized to the affected disk are the most common presenting features of spondylodiskitis, although it can be

asymptomatic and only detected on routine radiographic examination many years later.⁵³⁻⁵⁵ Spondylodiskitis usually occurs at an advanced stage of AS in the form of an erosive condition related to both mechanical factors and osteoporosis.^{54,55} However, early spondylodiskitis can occur as a result of the inflammatory process.⁵³⁻⁵⁵ Patients may or may not give a history of preceding trauma.⁵³⁻⁵⁶

The histologic appearance of these lesions can vary depending on the phase of the disease process.⁵⁶ During the initial inflammatory phase, there is marked lymphocytic infiltration. During the healing phase, reactive new bone formation with less inflammation is seen. Advanced lesions may show pseudoarthrosis with hemorrhage, fibrous tissue, callus formation, and sclerosis of the adjacent vertebral bone with few inflammatory cells.⁵⁶

Even trivial falls can be catastrophic for AS patients, who are at risk of spinal fractures due to their spinal rigidity and osteoporosis. The estimated prevalence of vertebral fractures in AS varies from 4% to 18%.⁵⁷ Fractures through the disk space, the weakest point in the ankylosed spine, are most common, with the cervical spine being the most frequently affected region, followed by the thoracolumbar junction.⁵⁸ Fractures may or may not be complicated by injury to the spinal cord, which can range from mild sensory loss to quadriplegia.^{57,59,60} One study found spinal fractures to be more frequent in AS patients with peripheral arthritis than in patients with only axial involvement.⁵⁸

Atlantoaxial subluxation

Spontaneous atlantoaxial subluxation is a well-recognized complication affecting about 2% of patients with AS, presenting with and without signs of spinal cord compression.^{61,62} The causes of atlantoaxial subluxation may be multifactorial, including transverse ligament damage by a periodontoid proliferative pannus or sequelae of ossification of the anterior and posterior longitudinal ligaments, associated inflammatory lesions (cervical spine osteoarthritis, atlantodental synovitis, erosions of the dens and adjacent ligaments), and physical stresses (kyphosis of the dorsal spine and weight of the head at the C1-C2 level).⁶¹

Neurologic manifestations

Neurologic involvement in AS is most often related to spinal fracture, atlantoaxial subluxation, or cauda equina syndrome. The cauda equina syndrome in AS is characterized by a slow, insidious progression and a high incidence of dural ectasia, although a rapid onset secondary to an event has been reported.^{63,64} It tends to be a late manifestation of AS, often when the disease is no longer active.⁶⁴ The prevalence of neurologic findings in cauda equina syndrome in AS is very high, and it presents with a prodrome of sensory, motor, or reflex loss before the progression to sphincter disturbance.⁶³ About half of patients have pain in the rectum or lower limbs that is presumably neurogenic in origin.⁶⁴ The pathophysiology is thought to include arachnoiditis and chronic inflammatory reaction, which may result in formation of dural ectasias and a slow progression of neurologic deficits.^{63,64} Another possible mechanism is reduced compliance and expansibility of the caudal sac resulting in excessive cerebrospinal fluid pulse pressure that over the years leads to a capacious caudal sac, enlarging arachnoid diverticula, secondary erosion into bone, and potential lumbosacral nerve root injury.⁶⁴ Tumor necrosis factor inhibitors have been used with success according to case reports.⁶⁵ Case reports have also been published describing the occurrence of AS with a multiple sclerosis–like syndrome and transverse myelitis, although the association is not conclusive.^{66,67}

Fatigue and psychosocial manifestations

Fatigue is a common problem in patients with AS and seems to be associated with more severe disease.^{68,69} Sleep disturbance has also been reported to occur in as many as nearly 81% of female AS patients and 50% of male AS patients. The disturbance is closely related to pain during the night characteristic of active disease.⁶⁸ A high level of depressive symptoms has been reported in approximately one third of patients with AS, with women reporting more depression than men.^{68,69} Pain was found to be a major determinant of depression in women but was of lesser importance in men.⁷⁰ In one study, self-reported measures of disease activity and mental health contributed significantly to explain fatigue, whereas clinical measures of inflammation and joint mobility did not.⁶⁹

Ankylosing spondylitis in women

AS may not be as severe in women as it is in men and may present with isolated neck pain in the absence of typical back pain.³ There tends to be a greater delay in the diagnosis of AS in women compared with men.³ Women tend to have less severe involvement of the spine with peripheral joint involvement.¹¹ After adjustment for degree of radiographic damage, women

appear to have worse functional outcomes than men.¹¹ A large review of the impact of AS on reproductive events in women concluded that AS did not adversely affect the ability to conceive, pregnancy outcome, or neonatal health. The disease did have an adverse effect, however, on the ability of the AS patient to cope as a mother and caregiver. Active disease at conception was a predictor of a postpartum flare.

INVESTIGATIONS

The most useful investigation in AS is musculoskeletal imaging, which is described in detail in Chapter 40, although some laboratory tests can be informative.

Data on the correlation of ESR and CRP level with disease activity in AS show ambiguous results, although most studies suggest that CRP performs better. A literature review examining the validity of ESR and CRP in AS concluded that ESR and CRP level do not comprehensively represent the disease process and thus do not have the same content validity as in rheumatoid arthritis. Generally speaking, it is felt that AS patients with peripheral joint involvement or with IBD, rather than those with axial disease, tend to have elevated ESR and CRP levels.^{71,72} However, a normal ESR and/or CRP level do not exclude the presence of clinically active AS.

A mild normochromic normocytic anemia may be detected.³ In severe disease alkaline phosphatase level may be elevated.³ Elevated serum IgA levels are common.³ Synovial fluid does not differ in appearance or cytologic findings from that in any inflammatory joint disease.³

DIAGNOSIS AND CLASSIFICATION

In most cases, AS is largely diagnosed, or at least initially suspected, on clinical grounds. There are no diagnostic criteria for AS, although there are recommended diagnostic algorithms.^{73,74} Classification criteria for AS and the larger category of SpA are reviewed in Chapter 113.^{1,75-77}

Natural history

Although AS is a chronic condition, it can have a variable course. Poor prognostic factors include hip disease, and risks of progression include elevation of inflammatory markers, smoking, and radiographic damage in the spine.^{78,79}

MEASURES OF ANKYLOSING SPONDYLITIS ACTIVITY AND SEVERITY

A number of measures have been developed to assess disease status in AS and are summarized in Box 114.1, including measures of disease activity, functional impairment, and quality of life. These instruments have been extensively validated, are easy to administer in clinical practice, and have been shown to perform well in clinical trials.

DISABILITY AND SOCIOECONOMIC IMPACT

Significant risk factors for work disability identified in several studies include older age, longer disease duration, lower level of education, reduced physical functioning, pain, and employment in more physically demanding

jobs.^{3,80-83} Prolonged standing at work or exposure to cold conditions are risk factors for disability.³ Patients with peripheral joint involvement are more likely to take sick leaves than those with only axial manifestations.³

Patients with AS have an overall frequency of disability and economic costs similar to those of patients with rheumatoid arthritis.⁸⁰⁻⁸³ The impact of agents such as anti-tumor necrosis factor drugs on the natural history of this disease appears promising, but their benefit remains to be confirmed.

LIFE SPAN

Survival may be reduced among patients with AS compared with the general population, and the standardized mortality ratio is higher in men than in women.⁸⁷ Causes of death include heart disease, cerebrovascular disease, malignancy, renal failure, pneumonia, suicide, and alcohol-related death, but the most common cause of death is cardiovascular disease.⁸⁴ Mortality risk appears to correlate with disease activity.⁸⁵

CONCLUSION

Axial spondyloarthritis and ankylosing spondylitis are regarded as the prototype and perhaps the most common type of SpA and are best characterized by the presence of chronic inflammatory back pain in the setting of radiographic sacroiliitis and frequently spondylitis and spinal limitation. In addition, common features of other types of SpA, both musculoskeletal (enthesitis and peripheral arthritis) and nonmusculoskeletal (uveitis and, less commonly, mucocutaneous, gastrointestinal, pulmonary and cardiac disease), are seen. Overall, it appears to be as disabling as rheumatoid arthritis, although advances in assessment as well as in imaging and treatment (detailed elsewhere) may greatly affect how and when it is diagnosed and treated and, ultimately, its natural history.

Etiology, pathogenesis, and pathophysiology of ankylosing spondylitis

■ DOMINIQUE BAETEN

- The etiopathology of ankylosing spondylitis (AS), the prototypic form of axial spondyloarthritis (SpA), may overlap only partially with that of peripheral SpA.
- HLA-B27 is the major susceptibility factor and is directly involved in the pathogenesis of disease, although it contributes only 20% to 30% of the entire genetic risk.
- HLA-B27 may contribute to disease pathogenesis through different mechanisms, including antigen presentation to CD8 T cells, direct stimulation of natural killer cells by HLA-B27 heavy-chain homodimers, and induction of an unfolded protein response in myeloid cells.
- Emerging evidence, including data on the non-antigen-dependent roles of HLA-B27 and the therapeutic failure of T- and/or B-cell-targeted therapies in AS, argues for a prominent role of innate immune cells rather than (autoreactive) lymphocytes.
- The role of bacterial and mechanical stress in disease induction and tissue predilection is consistent with a prominent autoinflammatory component.
- Tumor necrosis factor, interleukin-1 (IL-1), and IL-23/IL-17 are the major proinflammatory cytokine axes in SpA, with innate immune cells serving as the major source of these cytokines.
- Histopathologic examination of axial and peripheral lesions identifies specific changes in both innate and stromal cell populations, and a combination of bone destruction and new bone formation.
- Progression of new bone formation, an essential structural feature of AS, is partially disconnected from inflammation and bone destruction. Both BMP and Wnt signaling are important molecular pathways of osteoproliferation, but the factors leading to abnormal activation of these pathways remain unknown.

INTRODUCTION

The concept of spondyloarthritis (SpA) includes a number of associated disorders with common genetic, radiologic, and clinical features. Accordingly, the phenotypic presentation of SpA is diverse, which has led to a clinical subclassification into different subgroups depending on the symptoms that prevail: (1) ankylosing spondylitis (AS), in which spinal inflammation is predominant; (2) psoriatic arthritis, in which patients have cutaneous psoriasis together with spinal inflammation and/or arthritis; (3) reactive arthritis, in which an episode of acute infection of the gastrointestinal or urogenital tract is followed by spondylitis and/or arthritis; (4) inflammatory bowel disease-associated SpA, in which overt gastrointestinal inflammation is accompanied by spondylitis and/or peripheral arthritis; and (5) undifferentiated SpA, in which patients have SpA without any other specific symptoms that would allow a classification into the previously mentioned categories.

Although this phenotypic subclassification has obvious advantages in clinical practice and clinical research, one can question the degree to which it reflects different pathologic and pathogenic entities. First, the different conditions can occur consecutively in the same patient. Second, there are

often overlapping syndromes in which it is impossible to discriminate one specific subtype. Third, the different subtypes often affect different members of the same family. This familial aggregation can be explained largely by an important genetic component in the pathogenesis of the disease apart from the presence of similar environmental factors. This is illustrated by the fact that first-degree relatives of SpA patients have a risk of developing SpA that is 40-fold higher than that in the general population. Genetic studies in multiplex families have indicated that the clinical subclassification of SpA is not related to the underlying pathogenic mechanisms of the disease. More specifically, there is a random presentation of different clinical subtypes within multiplex families, which indicates that the genetic background does not account for the clinical subtypes but for SpA as a whole. The only exception to this rule is inflammatory bowel disease-associated SpA.¹

More recently, it has been proposed that SpA be subdivided based on the predominant musculoskeletal manifestation.^{2,3} In this classification, patients with symptoms arising primarily from inflammation of the axial skeleton are separated from patients in whom peripheral arthritis is the prevailing symptom. There is also evidence that the pathophysiologic mechanisms underlying peripheral SpA are distinct from those involved in exclusively axial SpA. First, patients with peripheral arthritis were found to be clustered in specific families in a study that included 329 SpA patients belonging to multiplex families.⁴ Because this was independent of the HLA-B27 status of the family members and disease duration, it strongly suggested that the development of peripheral synovitis is linked to the specific genetic background of the patients. Second, immunopathologic studies showed differences between axial and peripheral SpA. For example, matrix metalloproteinase-3 levels are specifically elevated in peripheral SpA⁵ and interleukin-17 (IL-17) is expressed mainly by myeloperoxidase (MPO)-positive cells in axial disease but by mast cells in peripheral synovitis.^{6,7} Third, therapeutic studies demonstrated a differential effect of non-steroidal antiinflammatory drugs (NSAIDs)⁸ and sulfasalazine⁹ in axial and in peripheral SpA.

In keeping with this genetic, pathophysiologic, and therapeutic evidence, the discussion here emphasizes the pathologic and pathophysiologic features of axial and peripheral SpA rather than using the phenotypic subclassification.

HLA-B27 AND THE ROLE OF T LYMPHOCYTES

The most important genetic risk factor for SpA is HLA-B27. The pathogenic role of this molecule has been formally demonstrated by the fact that overexpression in the rat leads to spontaneous SpA-like disease characterized by colitis, peripheral arthritis, spondylitis, uveitis, skin lesions, and orchitis.¹⁰ In support of the concept that SpA is one single disorder with different phenotypic manifestations, these rats display all the different features of human SpA, and the precise phenotype of the disease can be modulated by either environmental factors or additional genetic modifications. For example, the rats do not display colitis and peripheral arthritis in germfree conditions¹¹ and have more pronounced arthritis and spondylitis, but not colitis, in the presence of additional β_2 -microglobulin overexpression.¹²

Despite almost 40 years of intensive research, however, the precise role of HLA-B27 in SpA pathogenesis is still unknown. Three major hypotheses have been suggested (Fig. 115.1). The first and most logical explanation is the arthritogenic peptide hypothesis. This hypothesis is related to the antigen-presenting function of the HLA molecules and proposes that a specific peptide is presented in the context of HLA-B27, but not other HLA

molecules, and is presented to cytotoxic T lymphocytes, and that these cytotoxic T cells drive the pathologic process in SpA. This peptide could originate from bacteria, as suggested by the facts that gastrointestinal infections precede arthritis in the reactive arthritis subform of SpA and that May and associates¹³ demonstrated the clonal expansion of the same T-cell clones in the gut and joint of a patient with reactive arthritis. This suggests that the bacterial antigen-specific T-cell clones may recirculate to the joint and eventually be triggered by cross-reactive self-peptides derived, for example, from cartilage.¹⁴ The arthritogenic peptide hypothesis has been severely challenged, however, by two different studies demonstrating that CD8⁺ T cells do not appear to be crucial players in the HLA-B27 transgenic rat model.^{15,16} Moreover, recent observations indicate that antigen-presenting cells from HLA-B27 transgenic rats in fact show defective stimulation of naive helper T cells because of impaired engagement of the costimulatory molecules.^{17,18} In more general terms, a series of observations questions the role of T cells and the acquired immune system in SpA. First, individuals with SpA lack common genetic risk factors for classical autoimmune diseases such as polymorphisms in protein tyrosine phosphatase nonreceptor type 22 (*PTPN22*) and cytotoxic T-lymphocyte antigen 4 (*CTLA4*) genes. Second, SpA lacks the female predominance seen in most if not all autoimmune diseases. Third, individuals with SpA do not display disease-specific autoantibodies. And fourth, T- and/or B-cell-directed therapies are poorly effective or ineffective in at least the AS subform of SpA.¹⁹ Taken together, these data strongly suggest that SpA is not a classical autoimmune disease driven by self-reactive lymphocytes like rheumatoid arthritis (RA) or systemic lupus erythematosus.

ALTERNATIVE INNATE ROLES OF HLA-B27

Two alternative hypotheses have been proposed to explain the role of HLA-B27 in SpA (see Fig. 115.1). Both hypotheses relate to the presence of a cysteine residue in the β pocket of HLA-B27 that may lead to disulfide bonds and thereby abnormal structural organization of the HLA-B27 molecule. The first hypothesis proposes that HLA-B27 can form heavy-chain homodimers expressed on the surface of the cells.²⁰ These HLA-B27 homodimers can be recognized directly (i.e., independently of the antigen loaded on the major histocompatibility complex molecule) by killer-immunoglobulin-like receptors²¹ and thereby lead to activation of natural killer (NK) cells and T cells.²²⁻²⁴ The second alternative hypothesis is that HLA-B27 easily misfolds in the endoplasmic reticulum, which leads to the induction of unfolded protein response (UPR) and subsequent activation of a proinflammatory response program.^{25,26} It has now been established that the UPR induced by high HLA-B27 overexpression in bone marrow-derived rat macrophages²⁷ as well as by chemical agents in human dendritic cells²⁸ leads to abnormal production of cytokines, in particular IL-23, that could play a major role in SpA. Two key questions, however, remain to be answered in this context. First, it remains unknown whether physiologic expression of HLA-B27 as seen in SpA patients rather than nonphysiologic overexpression as observed in rats is sufficient to drive this proinflammatory program. Indeed, a recent report indicates that the increased production of cytokines, including but not restricted to IL-23, by peripheral blood monocyte-derived macrophages in AS is not related to manifest UPR.²⁹ Second, it remains to

be established whether the newly discovered susceptibility polymorphisms in the *ARTS1* gene have an influence on HLA-B27 misfolding, homodimer formation, and UPR. *ARTS1* codes for endoplasmic reticulum-associated aminopeptidase-1 (ERAP-1), a proteolytic enzyme that tailors peptides for presentation by class I molecules. ERAP-1 regulates both the amount of surface expression of class I molecules and the peptide repertoire presented by these molecules. Thus ERAP-1 polymorphisms could certainly play a key role in antigen presentation, as proposed in the arthritogenic peptide hypothesis, but may also influence the abnormal structural behavior of HLA-B27 as proposed in the two alternative hypotheses.

Although the exact, and not mutually exclusive, contributions of these different potential roles of HLA-B27 remains to be clearly established in human SpA, it is important to note that antigen-specific interactions with T cells are not central in either alternative hypothesis. Direct effects on NK and myeloid cells are thus compatible with a more central role for innate immune cells in the pathogenesis of SpA. Accordingly, SpA has now been proposed to be an autoinflammatory rather than autoimmune disease.^{30,31} A key feature of autoinflammatory diseases is that tissue-specific chronic inflammation is triggered by cellular stress. This concept fits well with (1) the role of gut luminal bacteria in the HLA-B27 transgenic rat model as well as human reactive arthritis and (2) the predilection of SpA for tissues subjected to intensive mechanical stress. The latter includes not only weight-bearing joints but also the enthesis and the underlying bone marrow. For this reason, an autoinflammatory theory of SpA may reconcile the role of HLA-B27, the anatomic predilection of the disease for tissues exposed to bacterial or mechanical stress, and, as is discussed in the next paragraphs, the role of specific innate cytokines and cell types.

INFLAMMATORY CYTOKINES IN SPONDYLOARTHRITIS

Additional insights in the pathophysiology of inflammation in SpA come from genetic and functional studies of specific cytokines or cytokine axes. An overview of the most important genetic risk factors for AS and SpA in general (Table 115.1) highlights the importance of three cytokine axes. First, the tumor necrosis factor (TNF) signaling pathway is genetically associated with AS. Obviously, the major pathogenic role of TNF in AS and SpA has now been very firmly established by the widespread use of TNF

TABLE 115.1
Major genetic susceptibility factors in ankylosing spondylitis (AS) and psoriatic arthritis (PsA),* ordered by chromosomal location

Genetic factor	Locus	AS	PsA
IL23R	1p31.3	Present	Present

inhibition in human patients. Intriguingly, however, the biology of TNF in SpA remains very poorly understood. Only very few if any data are available on which cells are the primary producers of TNF, whether TNF is produced mainly in its transmembrane or soluble form, which cells respond to TNF, and which receptor is crucial in this response in the context of SpA inflammation. One study demonstrated that, although SpA and RA show similar levels of overall inflammation, soluble TNF is lower in SpA than in RA, which indirectly suggests that TNF may act in its transmembrane rather than its soluble form in SpA.³² Using a TNF overexpression model in which mice develop severe colitis and destructive polyarthritis, another study elegantly demonstrated that expression of TNF receptor 1 on stromal cells was required for disease,³³ which suggests that stromal cells are one of the primary targets of TNF in SpA. Intriguingly, however, there is currently no clear indication that TNF blockade in human SpA significantly alters stromal remodeling and new bone formation, as is discussed in more detail later.

A second important cytokine is IL-1. Genetic studies now consistently indicate that IL-1 α is a susceptibility gene for AS.³⁴ In contrast to IL-1 β , IL-1 α is mainly an intracellular cytokine. The potential function of IL-1 α in SpA remains completely unexplored, but it is important to note that the IL-1 pathway is crucial to a large set of autoinflammatory diseases.

The third and most intensively studied cytokine axis is IL-23/IL-17. AS is genetically associated with IL-23 receptor (IL-23R) polymorphisms that are also linked to Crohn disease and psoriasis.³⁵ Taken together with the previously discussed upregulation of IL-23 by endoplasmic reticulum stress and the functional data indicating that the protective polymorphisms in the IL-23R gene are associated with impaired function of helper T 17 (Th17) cells,^{36,37} these data point toward a central role of IL-23/IL-17 in SpA. Although this role of IL-17 in the pathogenesis of AS has now been formally established in a still unpublished proof-of-concept trial using an anti-IL17A monoclonal antibody, the data on IL-23 and IL-17 expression in human SpA remain difficult to interpret. Systemic IL-23 serum levels are not markedly elevated and do not correlate with disease activity in SpA.³⁸ As for IL-17, reliable detection of serum levels remains a challenge. Studies measuring Th17 cells in peripheral blood have yielded mixed results, with most data indicating that the increase in circulating Th17 cells in AS is not specific and is also observed in other inflammatory conditions.³⁹ Two approaches have contributed here to our general understanding of IL-17-producing cells in SpA. First, analysis of very specific cellular subsets turned out to be more informative than a crude analysis of total numbers of IL-17-producing T cells. Among KIR3DL2-expressing T cells, which can be activated directly by the previously discussed HLA-B27 homodimers, the fraction expressing IL-17 is specifically increased in SpA.²³ Moreover, this fraction also shows a trend toward an increase in healthy HLA-B27+ individuals, which suggests that HLA-B27 may contribute to a proinflammatory, IL-17-oriented milieu. Another study carefully measured the IL-23R-expressing circulating leukocytes and found a specific increase in IL-17+ $\gamma\delta$ T cells in AS.⁴⁰ Second, the fact that inflammation in SpA is highly restricted to specific tissue environments prompted an analysis of IL-17 expression in axial and peripheral joints. Analysis of facet joints in patients with long-standing AS revealed IL-17 expression by CD15+ neutrophils, MPO+ innate immune cells, and, to a lesser degree, mast cells but not T cells.⁴¹ In peripheral SpA synovitis, IL-17 is mainly expressed by mast cells and, to a lesser extent, neutrophils.⁴² These data are in agreement with recent reports involving psoriasis.⁴³ Although it remains to be established whether neutrophils and mast cells really can produce IL-17 themselves, there is increasing evidence that they can at least release the protein and thereby contribute to local inflammation.^{42,44} The concept that innate immune cells rather than canonical CD4+ Th17 cells are the main cellular source of IL-17 is in agreement with the autoinflammatory rather than autoimmune nature of the disease. This concept is also further reinforced by a recent study showing that IL-23-responsive CD4–CD8– innate lymphoid cells present at enthesal sites drive localized tissue inflammation.⁴⁵ In this model, disease could be significantly ameliorated by both IL-17 blockade and IL-22 blockade. IL-22, however, appeared to play a more prominent role than IL-17, especially in the new bone formation program activated by IL-23 overexpression in these animals.

IMMUNOPATHOLOGY OF SPONDYLOARTHRITIS

A series of studies have assessed the histopathologic features of axial and peripheral SpA lesions. The resulting knowledge of cellular infiltration and inflammation helps to frame the pathogenic concepts in the context of human tissue inflammation.

In axial disease, one should distinguish the inflammation of the sacroiliac joints, the vertebral bodies, and the zygapophyseal joints. The sacroiliac joint is the most typical disease site in SpA. A detailed histomorphologic

study by François and colleagues of the sacroiliac joints of AS patients described the presence of inflammatory cells in the subchondral bone marrow as well as the synovial membrane, which can even form a small pannus.⁴⁶ In comparison with normal sacroiliac joints, there was significantly more superficial cartilage erosion, bone marrow edema, new bone formation, and bony ankylosis in the diseased joints. In analyzing the kinetics of the histopathologic changes, these authors described the presence of synovial inflammation and bone marrow edema as the earliest changes. This was followed by the formation of strings of connective tissue and new bone that eventually led to complete bony ankylosis of the joints. The presence of membranous as well as enchondral new bone formation was described. A second study used tissue obtained from the sacroiliac joint by computed tomography-guided needle biopsy.⁴⁷ Although it remains unclear whether the biopsy specimens represent genuine synovium because the characteristic intimal lining layer was not described, examination showed that the inflammatory infiltrate consisted of both T cells (CD4+ as well as CD8+) and macrophages.

Studies of vertebral bodies and intervertebral spaces in human AS are limited and indicate that the inflammatory cells are seen mostly in the annulus fibrosus, in association with erosion of the bone that makes contact with the annulus and a prominent neovascularization.^{48,49} The articulation between the vertebral bodies is formed by the zygapophyseal or facet joints. These synovial joints are frequently affected in SpA, with both the synovium and the subchondral bone marrow heavily infiltrated with inflammatory cells.⁴⁸ Identification of these inflammatory cells in the subchondral marrow space showed a predominant infiltration with T cells (CD4+ as well as CD8+) but also B lymphocytes.⁵⁰ Organized lymphocyte aggregates were present in 6 of 16 samples that were studied. In addition to bone marrow edema, there was also a prominent neovascularization in these samples. Unfortunately, the synovial membrane was not investigated in this study.

In peripheral SpA, an immunohistochemical study of femur heads of AS patients focused on the bone abnormalities, describing a pronounced infiltration of the subchondral bone marrow by T lymphocytes, with a predominance for CD4+ cells over CD8+ cells.⁵¹ In all samples, lymphocytic aggregates were present. Interestingly, the presence of T lymphocytes as well as osteoclasts was closely associated with the presence of cartilage in the close vicinity. Unfortunately, the presence of B cells and macrophages was not investigated in these samples. Although the synovial tissue was not investigated in this study of postsurgical femur heads, a series of studies has detailed the immunopathologic features of knee and ankle synovitis using synovial biopsy sampling in active disease. The inflamed synovium in both psoriatic and nonpsoriatic SpA contains a mixed inflammatory infiltrate that consists of macrophages, T lymphocytes, B lymphocytes, plasma cells, and a few neutrophils.^{52,53} The macrophages are the most prominent cellular population, and the majority of these cells express CD163, a scavenger receptor for heme-haptoglobin complexes.⁵⁴ An important role of these CD163+ macrophages in the local inflammatory process is suggested by the close correlation between the number of these cells and disease activity, both cross-sectionally and during effective treatment.^{55,56} These cells have now been identified as alternatively activated macrophages, and increasing evidence indicates that macrophage polarization is indeed biased toward this phenotype in SpA, whereas classical macrophage activation is seen in RA.^{32,57-59} The concept that specific innate immune cell populations are central to the immunopathologic characteristics of synovitis in SpA is further reinforced by the specific increase in mast cell infiltration and the specific upregulation of expression of Toll-like receptors 2 and 4 in SpA compared with RA.^{42,60}

Besides osteitis and synovitis, peripheral SpA is also characterized by enthesitis. There are two kinds of entheses: fibrous and fibrocartilaginous. Fibrocartilaginous entheses, which contain fibrocartilage, develop at the insertion of ligaments on bones that arise by enchondral osteogenesis, for instance, the calcaneum. Fibrous entheses develop at the insertion of ligaments on bones that arise by membranous osteogenesis, for instance, the iliac bone. In SpA, inflammation can occur in both types of entheses. Immunophenotyping of the infiltrate in SpA enthesitis was performed by two groups. McGonagle and associates sampled fibrocartilaginous tissue from the entheses of SpA patients by needle biopsy.⁶¹ CD68+ macrophages were the predominant cellular population in the inflammatory infiltrate in these samples. Laloux and associates sampled the entheses from the crucial ligaments and vastus lateralis of SpA patients by open surgery and focused on the changes in the subentheseal bone marrow.⁶² They described the presence of bone marrow edema together with an inflammatory infiltrate that consisted predominantly of CD8+ T lymphocytes. There was no increase in the numbers of macrophages in this tissue. Interestingly, both studies of enthesitis as well as most synovial studies described a pronounced neovascularization in the tissues.

JOINT REMODELING IN SPONDYLOARTHRITIS

A peculiar pathogenic feature of axial and peripheral SpA is that, unlike in RA, the chronic disease process leads not only to extensive bone and cartilage destruction but also to new tissue formation and even ankylosis. The previously mentioned histopathologic studies of the spine and the sacroiliac joints have confirmed that SpA structural abnormality is characterized by a combination of destruction and new bone formation. For example, the formation of bony bridges can be observed both in the granulation tissue, which penetrates into the joint from the bone marrow space after erosion of the bony endplate, and in the periarticular capsule of the facet joints in SpA. The exact nature of this bone formation process is unclear, however; some studies describe a predominance of membranous or reactive new bone formation, which is the direct transdifferentiation of fibroblastoid cells into osteoblasts, whereas other studies describe a predominance of endochondral bone formation, which is the formation of bone out of cartilage.

A number of important cellular and molecular insights into structural damage have started to emerge over the last years. First, it is now clearly established that the structural phenotype of SpA cannot be explained by the absence of destruction. In contrast, histologic, radiologic, and experimental evidence converge to indicate that bone erosions as well as the molecular and cellular machinery underlying these erosions are present and operative in SpA.⁶³⁻⁶⁶ Second, a number of molecular pathways have been identified that may drive osteoproliferation in SpA, in particular the BMP and Wnt signaling pathways.⁶⁷⁻⁶⁹ Although both pathways have been studied in animal models, it is interesting to note that biomarkers related to Wnt signaling are also associated with structural damage in human AS.^{70,71} Third, clinical and experimental studies have started to clarify the complex relationship between inflammation and structural damage in SpA. One hypothesis proposed that osteoproliferation in SpA is a repair mechanism triggered by an initial but transient inflammatory and destructive insult.⁷² Data from experimental models, however, indicate that complete prevention of early bone erosions does not impact osteoproliferation and, moreover, that osteoproliferation occurs simultaneously with pronounced inflammation and destruction (Fig. 115.2).^{66,73,74} Accordingly, radiologic data from clinical trials indicate that TNF blockade does not halt but also does not accelerate new bone formation. A second hypothesis proposes that the tissue remodeling and ankylosis is initiated by a common trigger but, once initiated, is completely uncoupled from inflammation.^{56,75} This hypothesis, however, is hard to reconcile with the fact that new bone formation is observed only in the presence of pronounced inflammation in experimental SpA.⁶⁶ Additionally, the genomewide association studies do not suggest primary genetic alterations in the bone formation pathways in AS. A third alternative hypothesis starting to emerge is that, in contrast to TNF-mediated inflammation, which promotes destruction and inhibits new bone formation, other types of inflammation may in fact drive osteoproliferation. This view is supported by recent data indicating a role of IL-22 in new bone formation in enthesitis⁴⁵ and by the observation that continuous and adequate NSAID treatment slows down osteoproliferation in AS.⁷⁶ Deciphering the exact mechanisms and interactions of joint remodeling and inflammation has become the major pathogenic and clinical challenge in the field of SpA research because it has crucial consequences for the timing and type of treatment.

INTERACTION BETWEEN INFLAMMATION, BONE DESTRUCTION, AND OSTEOPROLIFERATION

Fig. 115.2 Schematic representation of the interaction between inflammation, bone destruction, and osteoproliferation as observed in the spine of an HLA-B27/ β_2 -microglobulin transgenic rat model of spondyloarthritis. (a) Inflammation starts at the junction between vertebrae, intervertebral disk, and the enthesis. (b) Inflammation progresses toward the entire space between the cartilage endplate and annulus fibrosus; some inflammatory cells appear within the bone marrow. At this stage, the first signs of destruction (osteoclast-like cells and bone erosions) and remodeling (hypertrophic chondrocytes) appear. However, the remodeling process occurs at a distance from the site of inflammation. (c) Both inflammation, destruction, and remodeling become more pronounced over time. (d) Even when the joint is completely destroyed and normal anatomic structures have completely disappeared, the processes of inflammation, destruction, and remodeling is still ongoing. Red indicates inflammation; yellow indicates tissue destruction; and blue indicates bone remodeling.

Genetics of axial spondyloarthritis

■ MATTHEW A. BROWN ■ HUJI XU

- Susceptibility to and severity of ankylosing spondylitis, the prototypic axial spondyloarthritis, are highly heritable.
- Although HLA-B27 is the main genetic variant associated with axial spondyloarthritis, many other genes are involved in both HLA-B27+ and HLA-B27–disease.
- In particular, genes in the interleukin-23 response pathway and genes encoding aminopeptidases involved in peptide processing before HLA class I presentation are overrepresented among ankylosing spondylitis–associated variants.

GENETIC EPIDEMIOLOGY OF ANKYLOSING SPONDYLITIS

For more than 40 years, ankylosing spondylitis (AS) has been known to run in families. Familiality occurs because of shared susceptibility factors among family members, which may be environmental (random or common) or genetic.

Twin studies confirm that susceptibility to AS is almost entirely genetically determined, with two studies now formally estimating heritability as greater than 90%.^{1,2} Heritability of clinical manifestations of disease is also significant, with age of symptom onset, disease activity measured by the widely employed Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) and Functional Index (BASFI) questionnaires, and radiographic severity being 40%, 51%, 76%,^{3,4} and 62% heritable,⁵ respectively.

The association of HLA-B27 with AS is among the strongest genetic associations in any common disease, and yet studies in families suggest that less than 50% of the overall genetic risk is due to HLA-B27 and that it is likely that several other genes are involved. First-degree relatives of AS patients have a 5 to 16 times greater risk of developing AS than HLA-B27+ individuals in the general population, which implies the existence of factors modifying the risk of AS apart from HLA-B27.^{6,7} The most likely models of the disease suggest that genes modifying the effect of HLA-B27 determine the risk of getting the disease in HLA-B27 carriers.⁸ It is likely that, in addition to HLA-B27, there are a small number of genes with moderate effect and a large number of genes with small effect. Certainly, large multicausal families, which are typical in diseases with a monogenic cause, are extremely rare in AS. The risks of developing AS in different degrees of relatives to a proband with the condition are given in Table 116.1.

MAJOR HISTOCOMPATIBILITY COMPLEX GENES

The major histocompatibility complex (MHC) on chromosome arm 6p is strongly linked and associated with AS.^{9–15} Although most of the genetic association of this locus is driven by the association of AS with HLA-B27, the association is clearly more complex than that.

HLA-B27 and B27 subtypes

HLA-B27 is more common in Northern Europeans and is rare in Africans and Australian Aboriginals. The prevalence of AS generally follows the frequency of HLA-B27 in that population. In most studies, 80% to 95% of AS patients are HLA-B27+; thus in white Europeans the odds ratio for AS in HLA-B27 carriers is more than 50.^{16–18} Homozygous HLA-B27 carriers are

at an increased risk of AS compared with heterozygotes (odds ratio, 2.07; $P = .0025$).^{18–21} Despite that, only a minority of HLA-B27 carriers develop AS, and thus HLA-B27 has not been found useful in population screening. However, in patients with inflammatory low back pain, HLA-B27 testing is a useful component of the diagnostic workup (Fig. 116.1). This testing is further facilitated by the discovery of single nucleotide polymorphisms (SNPs) that accurately tag the HLA-B27 allele (rs116488202, sensitivity and specificity for HLA-B27 of 98.5% to 100% in white Europeans and East Asians), so that a cheap and robust SNP assay can be used rather than the more expensive and complex HLA-B27 assays.

There is strong evidence in specific populations that different subtypes of HLA-B27 have different strengths of association with AS. Over 90 HLA-B27 subtypes have now been reported (see the Anthony Nolan Trust database at <http://hla.alleles.org/class1.html>), with a rapid increase in the number of subtypes occurring over the past 5 years related to increased use of DNA-based HLA typing. In most cases the subtypes involved have been reported in only a few unaffected individuals, and therefore it is not possible to say whether or not they are associated with AS. However, some subtypes are sufficiently prevalent that the relative strengths of their association with AS can be compared.

AS (not just undifferentiated spondyloarthritis) has been reported to occur with the following subtypes of HLA-B27: *2702, *2703, *2704, *2705, *2706, *2707, *2708, *2710, *2714, *2715, and *2719. Until recently, no case of AS had been reported with B*2709, and this subtype is protective for the disease, relative to B*2705.²² Six cases with spondyloarthritis have now been reported in B*2709 carriers, although only two of these had classical axial AS, and in each case there were other potential explanations for the development of AS.^{23,24} These cases confirm that B*2709 is not absolutely protective for AS, although it is underrepresented in cases in Sardinia, due to its weaker association with disease than B*2705.

B*2706 similarly has been shown to be less strongly associated with AS than B*2704 in Southeast Asia, although these studies are complicated by ethnic differences in B*2704 and *2706 carriers, because B*2704 carriers are more likely to be of Chinese descent, whereas B*2706 carriers are more likely to be of Malay descent.^{24–27} There is increasing evidence that B*2704 is more strongly associated with AS than B*2705. A recent study in Taiwanese of Han Chinese descent supported this conclusion and also reported cases of AS in carriers of B*2706, confirming that the protective effect of this B27 subtype is not absolute.²⁸

Other major histocompatibility complex genes

The MHC, situated on chromosome arm 6 (6p21.3), extends over 3.6 megabases and contains about 220 genes, many of which have immunoregulatory functions. Although compelling evidence has been published suggesting that the HLA-B allele HLA-B60 is associated with AS, this finding was not supported by the large International Genetics of Ankylosing Spondylitis Consortium study, perhaps because of difficulties imputing HLA alleles using single SNPs rather than direct genotyping.¹⁸ This study did show that HLA-A*0201 is significantly associated with AS, although with a much smaller effect size than HLA-B27 (odds ratio of 1.21 in HLA-B27+ cases, 1.36 in HLA-B27– cases, compared with an odds ratio of 46 for HLA-B27 itself).

NON-MAJOR HISTOCOMPATIBILITY COMPLEX GENES

Association with the MHC explains less than half of the familiality of AS. Major advances have occurred in the last several years in identifying the

TABLE 116.1
Risk of ankylosing spondylitis in relatives of patients given HLA-B27 status

	B27 status unknown	B27+	B27–
Grandparent	1%	5%	0%
Parent/sibling	10%	15%	0%
Identical twin	60%	60%	?

Fig. 116.1 The x-axis shows the probability of ankylosing spondylitis (AS) before the HLA-B27 status is known. The likelihood of AS in the general population is approximately 0.5%; in a patient coming to a general practice with low back pain, the likelihood of spondyloarthritis is 5%. The posttest probability is the likelihood of AS given the prior probability of disease and the HLA-B27 status. The blue line represents the likelihood of disease (D) if the patient tests positive for HLA-B27, and the red line represents the likelihood if the HLA-B27 test result is negative.

non-MHC genes involved in AS. Starting with the discovery of the association of *IL23R* and *ERAP1* with AS,⁴ there have now been 31 loci reported to be associated with AS at genome-wide significance, and because at some loci more than one haplotype is disease associated, a total of 41 haplotypes have been identified. The current known replicated genes in AS are listed in Table 116.2, along with their relative contribution to the heritability of AS and putative functions.

In 2007 the first large-scale genome-wide association study to be performed in AS was reported by the Wellcome Trust Case Control Consortium (WTCCC) and the Australo-Anglo-American Spondyloarthritis Consortium (TASC).²⁹ The study identified and confirmed the association of SNPs in the genes *IL23R* and *ERAP1* with AS.

IL23R has also been demonstrated to be associated with both inflammatory bowel disease (IBD) and psoriasis. The three conditions AS, IBD, and psoriasis are closely related clinically. When cases with no history of either psoriasis or IBD are analyzed, the *IL23R* association with AS remains unchanged in the WTCCC/TASC data set, which indicates that AS itself is primarily associated with *IL23R* variants and is not secondary to the association of *IL23R* with IBD or psoriasis. Since this study the association of *IL23R* has been replicated in multiple white European populations, and findings in non-European populations are awaited. Fine-mapping and transethnic studies have confirmed that rs11209026 is the key associated SNP in white Europeans and that there is a second haplotype tagged by the SNP rs11209032, which lies between *IL23R* and the neighboring gene *IL12RB2*. In Behçet disease, an association is seen only at this second haplotype. In Asians, rs11209026 is nonpolymorphic, but another low-frequency protective allele with deleterious effects on interleukin-23 receptor (IL-23R) protein function is associated with AS (rs76418789, G149R).

In Crohn disease and ulcerative colitis, associations have also been reported with *STAT3*, *JAK2*, and *TYK2*, the genes encoding the signaling kinases and transcription factors associated with IL-23R signaling.^{30,31} This is in contrast to the findings in autoimmune diseases, in which strong association has been reported with *STAT4* in rheumatoid arthritis, systemic lupus erythematosus, and systemic sclerosis.^{32,33} *STAT3* is critical in the development of type 17 helper T lymphocytes (Th17), and individuals with monogenic conditions causing loss of *STAT3* have no Th17 lymphocytes and are extremely prone to extracellular infections.³⁴

The *IL23R* association with AS was the first suggestion that the IL-23-responsive and likely IL-17-producing lymphocyte pathways may be involved in the disease (see Chapter 115 for a discussion of the pathophysiology of AS). Although *IL23R* is also expressed on a number of other immunologic cell types such as macrophages, microglia, NK cells, NK T cells, and $\gamma\delta$ T cells, and it is not yet clear which cell type is primarily affected by the *IL23R* disease-associated variant (reviewed by Kenna and Brown³⁵). AS risk variants at *IL23R* have been shown to have greater function than protective variants, and it has been shown that IL-23 treatment induces enthesitis and psoriasiform skin lesions.³⁶ Many other genes in the IL-23R pathway have been found to be associated with AS, including *CARD9*, *TYK2*, *IL6R*, *PTGER4*, and *IL27*, which highlights the significance of this pathway to AS.¹⁷

Inhibition of IL-23 pathway activity is being investigated as a possible therapeutic approach for autoimmune disease. Antibodies to the IL-12p40 subunit (the shared IL-23/IL-12 subunit) have been studied with successful results in psoriasis³⁷ and Crohn disease,³⁸ and there are preliminary data to suggest that such therapies are effective in AS.³⁹

The other major finding of the WTCCC/TASC study²⁹ was the association of the gene *ERAP1* (formerly known as *ARTS1*), which is an aminopeptidase, the function of which is still being clarified. Since this original finding, the International Genetics of Ankylosing Spondylitis Consortium study has identified associations with loci harboring three other aminopeptidases, including *ERAP2*, *LN-PEP*, and *NPEPPS*, which indicates that this class of gene is critically involved in AS etiopathogenesis.¹⁸ The *ERAP1*-associated variant was associated only with HLA-B27+ AS, which indicates that it interacts with HLA-B27 to induce disease. The *ERAP2/LN-PEP* and *NPEPPS* associations are not HLA-B27 restricted. Interestingly, *ERAP1* variants have now been shown to be associated with HLA-Cw6+ psoriasis,⁴⁰ which suggests that HLA-Cw6 is involved in psoriasis pathogenesis by a mechanism similar to that by which HLA-B27 induces AS. *ERAP2* but not *ERAP1* has recently been associated with IBD; whether it interacts with any HLA variants is unknown.^{32,41}

The main associated variants at *ERAP1* and *ERAP2* are loss-of-function variants, which have been shown to reduce peptide trimming before HLA class I antigen presentation. The downstream effects of this reduction in trimming on peptide handling, HLA-B27 folding, and cell surface stability are still being elucidated, and it is possible that these *ERAP1* and *ERAP2* variants influence the peptide repertoire being presented by HLA-B27 either quantitatively or qualitatively.

ERAP1–/– mice are more prone to infection with *Toxoplasma gondii*, a vacuolar parasite, due to defective presentation of parasite antigen by the murine HLA class I system to CD8 T cells.⁴² This confirms a functional role of *ERAP1* in HLA class I-mediated immunity.

ERAP1 is expressed primarily in the endoplasmic reticulum, with two main functions reported. First, it may be involved in cleavage of cytokine cell surface receptors including IL-1R2, TNFR1 and IL-6R, downregulating their function,^{43–45} although *in-vivo* studies of this reported function have not confirmed this effect. Second, there is strong evidence that *ERAP1* is a key component of the peptide processing pathway before peptide loading into nascent HLA-class I molecules,^{46,47} such as HLA-B27. The crystal structure of *ERAP1* protein has now been determined, and it has been shown that the AS-protective variants either prevent closure of the catalytic domain by effects on its hinge regions or impinge on the catalytic site's capacity to engage with peptides.⁴⁸ The *ERAP2* protective haplotype carries a variant that causes nonsense-mediated decay of *ERAP2* messenger RNA and so is also a loss-of-function variant. The mechanisms underlying the genetic associations of *NPEPPS* and *LN-PEP* with AS remain to be determined. It also is not known whether the *ERAP1* and *ERAP2* variant associations operate by quantitative or qualitative effects on peptide handling. Whichever it is, it is clear that these associations are helping greatly in determining the mechanism of association of HLA-B27 with AS.

ANKYLOSING SPONDYLITIS IN EAST ASIANS

The prevalence of AS in Chinese populations is not dissimilar to that in white Europeans (0.2% to 0.54%), but the prevalence of the disease is low

TABLE 116.2

Genetic associations of ankylosing spondylitis (AS) and likely mechanism of action in the disease

Candidate gene	Gene locus	Contribution to genetic variance in AS (%)*	Putative functional significance
<i>IL23R</i>	1p31	0.352	Acts on IL-23R-expressing cells

in Japan, where HLA-B27 is rare. As in whites, AS in Chinese has a strong genetic background. However, the genetic association with AS in Chinese individuals has unique features. As in other ethnic populations, AS in Chinese is strongly associated with the class I MHC allele HLA-B27, which is found in more than 80% of Chinese AS patients compared with approximately 3% to 5% of healthy Chinese. Unlike the situation in many white populations, where B*2705 is largely predominant, in Chinese the main subtype is B*2704, with the majority of the remaining individuals carrying B*2705. Moreover, B*2704 appears to be the ancestor of a group of less frequent subtypes found in the Chinese population, including B*2715, which differs from B*2704 by a single amino acid changed at position 163.

In China, only 1% to 5% of HLA-B27 carriers develop AS, which suggests that although HLA-B27 plays a large role in disease susceptibility, there are other genetic factors responsible for modifying disease penetrance. So far, other genes that have been shown to be associated with AS in Chinese population include HLA-B60, *IL1A/B*, *STAT3*, *TNFRSF1A*, and *ERAP1*. As mentioned earlier with regard to *IL23R*, the actual associated allele at specific loci may differ among ethnic groups, although in most cases it is the same, consistent with a common ancestor origin of the disease-associated variant(s). The extent of genetic sharing between Chinese and Europeans is highlighted by a recent large-scale association study in which, of the 23 loci achieving genomewide significance in white Europeans, 13 showed at least nominal levels of association in East Asians (Chinese, Koreans, Taiwanese).¹⁸

One genomewide association study has been performed in Han Chinese alone, reporting the identification of two novel non-MHC loci at chromosome band 5q14 (between *HAPLN1* and *EDIL3*) and chromosome band 12q12 (*ANO6*).⁴⁹ Neither of these associations has been replicated in very large independent confirmation studies in either East Asians or white Europeans, and thus it seems likely that they are not AS associated.¹⁸

The common and unique genetic features of Chinese AS have shown the value of exploring the genetic diversity among different ethnic groups for gene mapping. These differences among various ethnic groups may possibly be used to distinguish true associations from artifact effects. Furthermore, identification of new susceptibility genes in Chinese may provide additional information on the pathogenesis of AS in white Europeans. This will make further gene mapping studies in East Asian populations very valuable in improving our understanding of the genetic basis of disease.

ANKYLOSING SPONDYLITIS IN AFRICANS

AS is rare in Africa, largely because of the rarity of HLA-B27, although even in rural African populations where HLA-B27 is prevalent, AS is rare.^{50,51} This is not due to differences in the HLA-B27 subtypes present because AS has a lower prevalence even in Africans carrying the European subtype HLA-B*2705.⁵² African Americans do get AS, which indicates that the rarity of the disease in Africa is likely to have an environmental component, in addition to the effect of the low prevalence of HLA-B27. Little has been reported

about the clinical or genetic manifestations of AS in African Americans. A recent case series reported more severe disease and a lower prevalence of HLA-B27 in African American than in white AS cases (62% vs. 84%, respectively),⁵² consistent with previous reports.⁵³

SUMMARY AND CONCLUSIONS

The field of the genetics of AS is progressing rapidly and has already contributed much to our understanding of the disease etiopathogenesis, in particular implicating the IL-23-responsive lymphocyte subset as being

important in the development of the AS. A significant proportion of the overall genetic risk in AS has yet to be determined, and no genes have yet been identified that contribute to the clinical manifestations of the disease. Identifying genes involved in these processes will assist in the development of novel therapies for AS, for which no treatment is currently available that has been shown to alter the natural history of the disease.

Imaging in spondyloarthritis

■ JUERGEN BRAUN ■ XENOFON BARALIAKOS

- MRI is the gold standard for assessment of inflammatory changes in the sacroiliac joints and the spine of patients with axial spondyloarthritis.
- Conventional radiographs are still the gold standard for assessment for chronic/postinflammatory changes but the knowledge about the use and interpretation of these changes by MRI is increasing.
- Definitions for a positive MRI of the sacroiliac joints and the spine for use in the Assessment of SpondyloArthritis international Society classification criteria have been recently published.

INTRODUCTION

Axial spondyloarthritis (axSpA)—a new term that covers both “classical” ankylosing spondylitis (AS) and non-radiographic axial spondyloarthritis¹—is a chronic inflammatory rheumatic disease that affects mainly the axial skeleton, whereas patients with predominantly peripheral spondyloarthritis (SpA) have mainly arthritis, enthesitis, and dactylitis.¹ The pathognomonic findings of axSpA are inflammatory, osteodestructive, and osteoproliferative changes in the sacroiliac joints (SIJ) and spinal structures, many of which are enthesal in nature. Clinically, these pathologic changes lead to chronic inflammatory back pain, although some patients report only increasing spinal stiffness.^{2,3} The whole group of spondyloarthritides shares other characteristic clinical symptoms caused by extraarticular manifestations such as acute anterior uveitis, psoriasis, and inflammatory bowel disease. Rare but typical manifestations of AS are aortic valve disease and cauda equina syndrome. Frequent comorbidities are osteoporosis and cardiovascular disease.

Sacroiliitis, spondylitis, spondylodiskitis, and spondyloarthritis are the main inflammatory manifestations in the axial skeleton⁴ and may lead to new bone formation occurring as syndesmophytes and ankylosis in the vertebral column; about 15% of AS patients even develop bamboo spine.⁵ Peripheral manifestations are found mainly in the root joints, the hips, and the shoulders but also are seen at many entheses such as the heel (Achilles tendon, plantar fascia), the knee (pes anserinus) and the elbow (epicondyle).

These characteristic changes may occur during the course of the disease in many patients. However, the frequency of these manifestations as well as the velocity of disease progression and severity vary among patients.⁶ The complex pathogenic process involving inflammation and transformation to structural changes in axSpA is still incompletely understood. One important aspect in this regard is the parallel occurrence of inflammatory, osteodestructive, and osteoproliferative but also osteoporotic changes in the vertebral column.⁷ Although the effect on the spine consists largely of new bone formation, the involvement of the peripheral joints clearly is erosive.

Different imaging techniques are relevant for diagnosis, classification, assessment of disease activity and structural damage, and prognosis in patients with axSpA. The capacity of the various techniques to detect potential pathologic processes clearly is different. Conventional radiographs currently are still considered the gold standard for assessment of structural changes in the axial skeleton of patients with axSpA.^{4,5} Computed tomography (CT) is useful for the detection of structural changes in the SIJ because of its superior sensitivity and specificity compared with conventional radiography, especially when the absence of structural changes needs to be documented. However, both methods are unable to visualize active inflammation. The best method to detect inflammatory changes is magnetic

resonance imaging (MRI). The use of scintigraphy is not recommended because of the very low specificity of this technique.⁸

Peripheral joints affected by the disease increasingly are assessed using ultrasound techniques, and the knowledge in this field has grown remarkably in the last decade.⁹ Therefore the different imaging techniques currently available for evaluation of axSpA should be used in complementary fashion and according to individual indications (Table 117.1).

Only changes in the SIJ are considered relevant in the current classification criteria for axSpA and AS. Nevertheless, some patients may show spinal involvement in the absence of abnormalities in the SIJ.⁴

The magnitude of the pathologic changes in the axial skeletons of patients with axSpA is used to quantify inflammatory and structural outcomes in clinical trials involving axSpA. Different scoring systems have been proposed for the assessment of inflammatory and structural changes in axSpA.¹⁰⁻¹²

The prognostic relevance of structural changes (presence of syndesmophytes by radiography) and of the degree of inflammatory changes in the SIJ (by MRI, in combination with HLA-B27 testing) has been well demonstrated.¹³

TECHNICAL ASPECTS OF IMAGING IN AXIAL SPONDYLOARTHRITIS

For imaging of the SIJ, different orientations are used depending on the imaging technique. For conventional radiography, the orientation used is the anteroposterior (AP) view. This is the most common view for assessing the SIJ, in combination with either the lumbar spine, including the thoracolumbar junction (Fig. 117.1a), or the pelvis and hip joints (see Fig. 117.1b), depending on the location of the patients' symptoms. In addition, the Barsony technique (patient in the supine position, AP projection, the tube angled at 10 to 25 degrees toward the head; see Fig. 117.1c and d) or the Ferguson technique (patient in the prone position, posteroanterior projection, the tube angled at 25 to 30 degrees toward the head) is used for imaging solely of the SIJ. However, a clear advantage of these views has not been established to date.

Imaging with CT and MRI has the general advantage of providing multidimensional images through a technique in which the anatomic region of interest is cut into slices and digital processing of the data is performed. Pathologic processes can then be visualized in different orientations and planes. The most commonly used orientation in the case of the SIJ is the semicoronal plane (parallel to a line tangent to the upper posterior portion of S1 and S3), but a semiaxial view (perpendicular to the semicoronal orientation) can also be produced to provide additional information.^{14,15}

In the evaluation of the spine, the sagittal orientation is most frequently used in all imaging techniques. In conventional radiography the AP view is also frequently used to increase the sensitivity for detecting syndesmophytes. In CT and MRI the slices should cover the whole vertebral body, including the posterior elements (spinous processes) as well as the lateral elements (facet joints). Because of the digital nature of these techniques, coronal or axial (transverse) views can also be generated but do not need to be produced on a routine basis.

Technical aspects of magnetic resonance imaging

For the assessment of bone marrow edema as a sign of inflammation in axSpA, the short tau inversion recovery (STIR) sequence, the T2 fat-suppressed sequence, and the T1-weighted sequence performed after administration of intravenous contrast agent (gadolinium–diethylenetriamine pentaacetic acid [T1/Gd-DTPA]), with or without additional fat-suppression

sequences, are recommended.³⁵ For routine imaging, the STIR sequence (see Fig. 117.4a) is usually sufficient because of the strong suppression of the fat signal, which leads to very good fat-water contrast.⁷

Soft tissue involvement around the SIJ such as synovitis, capsulitis, and enthesitis is better detected using T1/Gd-DTPA sequences. However, such changes are not considered highly specific for axSpA, and the use of gadolinium is more expensive, is time consuming, and is contraindicated in

patients with impaired renal function, which makes this technique less feasible for routine practice.

There is some evidence that STIR is 90% compatible with imaging techniques using post-gadolinium T1-weighted sequences in imaging of the SIJ.⁷ The use of dynamic MRI of the SIJ, as proposed earlier,³⁷ is no longer recommended because it produced too many positive but nonspecific results.

For the assessment of structural lesions, the T1-weighted turbo spin-echo sequence, a standard technique that is usually performed before the administration of a contrast agent, is frequently used, but gradient-echo techniques also have been recommended because of their ability to show cartilage abnormalities.⁷

Protocols for MRI examination of the SIJ currently are based on the use of a 1- to 1.5-T superconducting whole-body magnet with a body phased-array coil. For STIR sequences the following parameters are most frequently used: TR/TE/TI: 4000/60/150 ms, slice thickness 3 or 4 mm. The parameters for a T1 sequence are TR/TE: 500/10 ms; for a T1 with fat suppression (T1 FS): TR/TE: 660/16 ms; and for a T2-weighted gradient-echo sequence: TR/TE 180/7.15 ms.

IMAGING OF THE SACROILIAC JOINTS IN AXIAL SPONDYLOARTHRITIS

Imaging of the SIJ is critically important for diagnosis and classification in axSpA because the vast majority of patients with axSpA show involvement of this part of the axial skeleton, especially in early stages of the disease. For example, a certain degree of structural changes in the SIJ is a prerequisite for the classification of AS according to the 1984 modified New York

Fig. 117.1 (a) Conventional radiograph of the sacroiliac joints and the thoracolumbar junction in a patient with established ankylosing spondylitis. (c, d) Barsony technique for imaging of the sacroiliac joints in ankylosing spondylitis.

criteria¹⁶ and for classification of axSpA according to the Assessment of SpondyloArthritis international Society (ASAS) criteria published in 2009.¹

Conventional radiography

As the initial approach in a patient suspected of having axSpA, radiographs are the gold standard for assessment of structural changes in the SIJ. Typical findings are sclerosis, erosions or pseudodilation, and/or bony bridges (Fig. 117.2). The method used for quantification of structural changes in the SIJ in clinical practice¹⁷ has been derived from the modified New York criteria for classification of AS.¹⁶ Importantly, for this evaluation, the age of the patient needs to be taken into account, because bony changes in the SIJ frequently may be found in the elderly population as a feature of osteoarthritis. For a diagnosis of axSpA in early disease stages conventional radiography has limited value because of its poor sensitivity due to the inability of the method to detect active inflammation.¹⁸ Routine imaging of patients with low back pain to detect chronic SIJ changes did not provide substantial additional information in one study,¹⁹ but results may be different in younger patients who have inflammatory back pain and in whom the suspicion of axSpA is high.⁴ There is some evidence that structural changes in the SIJ may develop rather rapidly.²⁰

Computed tomography

For the detection of structural changes in the SIJ, CT (Fig. 117.3) has proven more useful than conventional radiography because it provides superior multidimensional imaging of anatomic structures by cutting the SIJ into slices.²¹⁻²³ This is advantageous because of the complicated anatomy of the SIJ caused by the irregular S-shaped orientation and the partly overlapping structures of the sacral and iliac joints.²⁴

With CT, however, as with radiography, findings of sclerosis, joint space narrowing, erosions, and ankylosis may be misleading in elderly patients,²⁵ since subchondral sclerosis of the SIJ, especially in the iliac portion, is a phenomenon of aging, as is joint space narrowing.⁷

CT-guided techniques to biopsy and inject the SIJ²⁶ have been used in experienced centers with some success.²⁷

One general note is that the radiation exposure associated with CT needs to be taken into account when a decision is made regarding imaging method. This radiation exposure is the reason that CT is not recommended for the evaluation of patients with low back pain and suspected SpA in daily practice.

Scintigraphy

The nuclear-medical method of scintigraphy takes advantage of the physical behavior of the radionuclide technetium-99, which enriches in areas of increased metabolism or inflammation. Therefore scintigraphy of the SIJ frequently was used in the past to detect sacroiliac and/or spinal inflammation in patients suspected having of axSpA.²⁸⁻³² However, because the sensitivity and specificity of other imaging techniques such as MRI were shown to be superior, its use has decreased substantially in recent years.^{8,33} The results of scintigraphy of the SIJ seem to be more reliable if there is unilateral involvement consistent with clinical symptoms. Therefore, since scintigraphy as a tool to detect sacroiliitis has clear limitations, it is not suitable for the diagnosis of axSpA. Whether scintigraphy can be of use as a more general tool for detecting enthesal inflammation in different regions at a time remains to be elucidated. As with CT, the radiation exposure needs to be taken into account when young patients with low back pain are being evaluated.

Magnetic resonance imaging

One of the major advantages of MRI is the detailed anatomic and pathologic imaging it affords in connection with the information provided on the location of inflammation. MRI is especially useful for detecting bone marrow edema as a sign of osteitis in the axial skeleton in patients with axSpA (Fig. 117.4a). MRI is also able to visualize the complicated anatomy of the region of the SIJ; this includes characteristic abnormalities of the periarticular soft tissue, which are only indirectly visible by other methods (Table 117.2). Sacroiliac inflammation as detected by MRI ("water signal") has been shown to correlate with conventional histologic and immunohistologic findings and to some degree with clinical symptoms of axSpA as well.¹⁴ MRI has also been used to detect more chronic structural changes of bone and joints. The typical structural changes in patients with axSpA are periarticular fat deposition, subchondral erosions, sclerosis (see Table 117.2, Fig. 117.4b), and

Fig. 117.2 Typical radiographic findings of sacroiliac joints involvement in a patient with ankylosing spondylitis, showing extensive sclerosis (left arrow), pseudodilation (right arrow), and partial ankylosis (asterisk).

Fig. 117.3 Computed tomographic scan of the sacroiliac joints of a patient with ankylosing spondylitis. Note the areas with erosions (arrows) and sclerosis (asterisks), which represent characteristic signs of the disease.

Fig. 117.4 Magnetic resonance image (MRI) of the sacroiliac joints of a patient with ankylosing spondylitis. Bone marrow edema (osteitis) is visible as hyperintense signal in the short tau inversion recovery (STIR) sequence (a) and as hypointense signal (thick arrows) in the T1-weighted sequence (b). Postinflammatory changes such as fat deposition are visible as hyperintense signal in the T1-weighted sequence and hypointense signal in the STIR sequence (asterisk). Structural changes (erosions) are seen in both sequences (thin arrows). In cases where more than one inflammatory lesion or a large periarticular lesion is present on one slice, this MRI finding is highly suggestive of axial spondyloarthritis.

TABLE 117.2

Characteristic lesions in the sacroiliac joints of patients with ankylosing spondylitis as revealed by magnetic resonance imaging

Tissue	Inflammatory changes	Structural changes
Bone marrow	Sacroiliitis (bone marrow edema, osteitis) in one or both parts of the sacroiliac joint (sacral or iliac). Bone marrow edema related to spondyloarthritis is located periarticularly.	Subchondral sclerosis Erosions Fatty deposition
Synovium	Synovitis. Shown only by T1/Gd-DTPA sequences. STIR sequences cannot differentiate between synovitis and physiologic joint fluid. Synovitis is a rare lesion.	Bony bridges/ankylosis
Joint capsule	Capsulitis. Comparable to synovitis. Both anterior and posterior joint capsule can be affected.	Bony bridges/ankylosis
Ligaments	Enthesitis, seen in the junction of ligaments and tendons with the bone.	Degeneration of ligament

Gd-DTPA, gadolinium diethylenetriamine-pentaacetic acid; STIR, short tau inversion recovery.

bony bridges or ankylosis. The fat signal in particular has raised interest because this element cannot be detected by conventional radiography.³⁴

Even though structural changes in the SIJ as demonstrated by MRI are not included in the current ASAS classification criteria¹ and the definition of positive findings on MRI,³⁵ there is some evidence that lesions such as fatty changes and erosions may contribute to the diagnostic usefulness of MRI in axSpA.³⁴ However, it is not clear whether MRI can substitute for radiography to optimize the diagnosis of chronic changes, and an international agreement on clear-cut definitions has not been achieved to date (see later).

Importantly, and in contrast to other imaging techniques, MRI is not associated with radiation exposure. This makes the technique especially useful in young women, children, and patients with a suspected future risk of relevant radiation exposure. However, routine access to MRI, optimal technical equipment, and skilled staff is not widely available, and the costs of MRI are still higher than those of other imaging techniques.³⁶ Furthermore, patients with claustrophobia, pacemakers, or metal implants cannot be examined by MRI. In addition, because of the long duration of the procedure (approximately 20 to 30 minutes) use of the technique is not feasible in some patients because of intolerable pain and stiffness in the supine position.⁷

Definition of a positive finding on magnetic resonance imaging of the sacroiliac joint in axial spondyloarthritis

According to the ASAS definition, the hyperintense/inflammatory signal in the bone marrow near the SIJ should preferably be located in the periarticular region. The MRI finding for the SIJ in patients with axSpA is considered positive when more than one lesion is present on a single MRI slice or, if there is only one lesion, it is present on at least two consecutive slices³⁵ (see Figs. 117.4 and 117.5).

Differential diagnoses for involvement of the sacroiliac joint

Bone marrow edema is not a specific feature of axSpA and may also occur in other diseases. The most important differential diagnoses for active changes in the SIJ are septic sacroiliitis, osteitis condensans, and pelvic fractures, and those for chronic changes are extensive sclerosis or structural changes caused by degenerative conditions.

In the case of septic sacroiliitis, conventional radiographs usually show normal findings in the first weeks of disease,⁷ whereas MRI is capable of demonstrating the pathologic process much earlier.^{38,39} Therefore MRI is considered the gold standard for a diagnosis of septic sacroiliitis. The major differential diagnostic criterion is that the infection passes the mark of anatomic borders, so that the proximal parasacroiliac structures, including

Fig. 117.5 Example of a positive finding on magnetic resonance imaging of the sacroiliac joints in axial spondyloarthritis. When only one lesion is seen, this lesion must be present in at least two consecutive slices (arrows).

the iliopsoas muscle, may be infiltrated. Fractures are mainly seen as insufficiency fractures and are characterized by a bone marrow edema that may be similar to that seen in sacroiliitis.

The MRI finding of extensive sclerosis, especially at the iliac side of the SIJ, may also be misleading. Osteitis condensans ilii, characterized by a triangular sclerosis, is found most often in women after pregnancy, but it may rarely occur in men as well. In diffuse idiopathic skeletal hyperostosis (Forestier disease), the typical findings are an irregularly shaped SIJ, including sclerosis, ossification of the joint capsule, and bony bridges, many of which may be difficult to differentiate from axSpA. However, such changes usually do not occur in young patients.

IMAGING OF THE SPINE IN AXIAL SPONDYLOARTHRITIS

Spinal changes, usually representing more advanced stages of the disease, may be clinically relevant for a diagnosis of axSpA, but they have never been part of the classification criteria for AS or axSpA. One reason is that only 3% to 5% of patients with AS were reported not to have unequivocal structural changes in the SIJ.⁴⁰ The other reason is the similarity of syndesmophytes to spondylophytes of a degenerative nature, especially in patients with disease of longer duration.

Therefore the current clinical significance of syndesmophytes is to support a diagnosis of axSpA in individual patients with indefinite SIJ findings. Furthermore, syndesmophytes have definite prognostic value, since the presence of one syndesmophyte has been shown to increase significantly the risk of development of more such changes.⁵ How much time is required for structural lesions of the spine to develop is not clearly known. Within the first 16 years of AS, bony changes have been reported to be present in more than 50% of patients.⁴¹

Both inflammatory and structural spinal changes play an important role in the evaluation of medical interventions, since the effect of anti-inflammatory agents such as non-steroidal anti-inflammatory drugs or tumor necrosis factor blockers on spinal inflammation (bone marrow edema) and new bone formation (syndesmophytes) are relevant objective outcomes in clinical studies in axSpA patients. However, clinical symptoms, including pain, stiffness, and decreased function, are considered even more important.

Conventional radiography

As for the SIJ, conventional radiography has a low sensitivity in detecting inflammation of the spine such as spondylitis, SpA, or spondylodiskitis.⁴² Nevertheless, conventional radiographs are the gold standard for the assessment and quantification of structural spinal changes. The visualization of osteodestructive and osteoproliferative processes in the vertebral bodies (Fig. 117.6) is useful to assess the course of the disease and the damage that has already occurred. Pathologic spinal changes related to axSpA can be differentiated in osteodestructive changes (erosions) and hyperproliferative changes (enthesophytes, vertebral squaring, disk calcifications, spondylophytes, syndesmophytes, bony bridging, vertebral ankylosis). Syndesmophytes are characterized by their typical vertical growth, which may lead to

Fig. 117.6 Typical osteodestructive changes seen as erosion (asterisk) and osteoproliferative changes seen as syndesmophytes (arrows) on a radiograph of the cervical spine of a patient with ankylosing spondylitis.

Fig. 117.7 Next to the vertebral bodies, also facet joints are frequently affected in ankylosing spondylitis, showing hyperproliferation and ankylosis (arrows).

bridging phenomena in the prediskal region between the intervertebral disk and the anterior intervertebral ligament.⁴³⁻⁴⁵

Furthermore, the lateral parts of the vertebral bodies and the facet joint area deserve attention, since they are frequently affected in AS (Fig. 117.7). Because these areas are difficult to assess by most imaging procedures, involvement of the facet joints is frequently underdiagnosed. Ankylosis of the facet joints may be discordantly associated with the presence of bridging syndesmophytes in established AS,⁴⁶ which suggests that these joints are involved primarily and early in the course of the disease.

Magnetic resonance imaging

For the spine as for the SIJ, MRI is considered the most sensitive method for the detection of inflammatory lesions related to axSpA.^{47,48} Assessment of spinal inflammation on MRI can be used as an indicator of disease activity, as a tool for evaluating response to biologic treatment, and also as a possible predictor of response to therapy.⁴⁹ Overall, spinal MRI performs best in the identification and quantification of active spinal lesions (Table 117.3, Figs. 117.8 and 117.9), for which it has proved superior compared with other

TABLE 117.3

Characteristic lesions in the spines of patients with ankylosing spondylitis as revealed by magnetic resonance imaging

Tissue	Inflammatory changes	Structural changes
Vertebral body	Inflammation (spondylitis) in the bone marrow, mainly in the corners	New bone formation (syndesmophytes, ankylosis), eventually erosions or destruction of the vertebral body (e.g. fracture) Fatty degeneration
Intervertebral disk	Inflammation (spondylodiskitis)	Ossification of the disk
Facet and costovertebral joints	Inflammation with or without involvement of the vertebral body	New bone formation and ankylosis in advanced stages
Ligaments	Enthesitis, mainly of the supraspinal and interspinal ligaments	Degeneration of ligaments

Fig. 117.8 Magnetic resonance images showing (posterior) spondylitis and inflammation of the facet joints (arrows).

imaging techniques.^{47,50} T1-weighted MRI has also been used successfully to assess structural changes (see Table 117.3, Fig. 117.10a).⁵⁰

Typical findings of disease activity when using spinal MRI in patients with axSpA are spondylitis, inflammation of the facet joints, and spondylodiskitis (see Fig. 117.8).

Spondylitis is a pathognomonic sign of bone marrow edema related to axSpA and has been considered as an early sign of spinal involvement in the disease (see Fig. 117.8). It represents an active osteitis and enthesitis at the junction of the annulus fibrosus and the longitudinal ligaments with the anterior ligament, the vertebral body, and the intervertebral disk. When MRI is used, spondylitis is typically seen as a hyperintense signal in STIR or T1/Gd-DTPA sequences with a corresponding hypointense signal in T1-weighted sequences. In later stages, the pathologic signal is inverted as a sign of a healing process and local tissue metaplasia with occurrence of fatty lesions, which shows as hyperintensity in T1-weighted images and hypointensity in STIR (or T1/Gd-DTPA) sequences. There is evidence that the posterior vertebral edges are more frequently involved in early stages of AS.⁵¹

Inflammatory lesions in the *facet joints* are also characterized by hyperintense signal in MRI sequences sensitive to depiction of inflammation (see Fig. 117.8) and hypointense signals in T1-weighted sequences. Active and structural changes of the facets and especially of costosternal and costovertebral joints in AS may lead to reduced chest expansion—a relatively frequent finding even in young AS patients. If clearly pathologic (age does have

Fig. 117.9 (Abacterial) spondylodiskitis (formerly known as Andersson lesion) in established AS, typically recognized by a circumscribed hemispherical erosive lesion surrounded by bone marrow edema in STIR and the corresponding hypointense signal in T1-weighted MRI.

Fig. 117.10 “Positive MRI” of the spine for inflammatory changes, highly suggestive for axial SpA, with three vertebral corners being affected by bone marrow edema (a). Positive MRI of the spine for chronic changes, highly suggestive for axial SpA, with several vertebral corners being affected by fatty degenerative changes (b).

an influence on thoracic excursion), it can even be used as a diagnostic sign in AS.¹⁶

Spondylodiskitis is characterized by a circumscribed hemispheric erosive lesion, which is often surrounded by an area of bone marrow edema in one of two adjacent vertebral bodies. In contrast to conventional radiography, in which only the consequences of spondylodiskitis are visible in later disease stages as areas with sclerosis, MRI is able to detect such changes even in early phases^{52,53} (see Fig. 117.9). Accordingly, negative radiographic findings are sometimes accompanied by positive MRI findings indicative of spondylodiskitis.^{52,53} Asymptomatic spondylodiskitis occurs in multiple spinal segments in approximately 8% to 15% of patients with AS,^{42,54} whereas such findings are apparent in up to 31% of patients with enteropathic SpA.⁵⁵

Definition of a positive finding on magnetic resonance imaging of the spine in axial spondyloarthritis

According to the ASAS definition of a positive finding on MRI of the spine in axSpA,⁴⁸ bone marrow edema preferably should be located in the corner of the vertebral bodies. Evidence of anterior-posterior spondylitis in three or more vertebral corners is considered to be highly suggestive of axSpA (Fig. 117.10a), especially in patients of younger ages at which degenerative

Fig. 117.11 Spinal radiograph showing degenerative changes (arrows) in a patient with ankylosing spondylitis. Such changes are differentiated by syndesmophytes due to their horizontal growth. Ankylosis of the facet joints is also visible (asterisks).

changes play a minor role in the differential diagnosis. As for chronic changes, fatty deposition at several vertebral corners also may be indicative of axSpA (Fig. 117.10b). Detection of fatty deposition at vertebral corners, particularly if present at several sites, increases the likelihood of axSpA, especially in younger patients. There is limited information on the appearance of bone changes in early phases of diffuse idiopathic skeletal hyperostosis.

Differential diagnoses for involvement of the spine

As with the SIJ, bone marrow edema of spinal structures is not specific for axSpA but may also occur in other diseases. The most important differential diagnoses are degenerative changes, blood vessels and hemangioma, fractures, bacterial infection, and hyperproliferative changes due to other conditions.

Degenerative changes are seen on radiographs as osteophytes that grow in a horizontal direction (spondylophytes)⁵ (Fig. 117.11). The most typical degenerative changes on MRI are so-called erosive osteochondrosis or Modic lesions, which are a frequent finding in association with chronic back pain in patients of every age. These changes are recognized by the presence of bone marrow edema of the vertebral endplate accompanied by decreased disk height (Fig. 117.12). Similarly, Scheuermann disease starting in childhood is characterized by irregularities in the upper or lower part of the vertebral endplates and erosive changes on the vertebral surface, which often are not recognized before adulthood.

Diffuse idiopathic skeletal hyperostosis (DISH, Forrester's disease; Fig. 117.13) is characterized by bulky osteophytes, which often exceed the length of the anterior longitudinal ligament. Differentiating between the typical ankylosing processes in AS and DISH is sometimes difficult. Nevertheless, a radiographic differentiation between AS and DISH is possible because the shape of the spinal osteophytes differs. Typical syndesmophytes are much more frequent in AS, whereas DISH is characterized by degenerative spondylophytes and spondylosis.⁵⁶

Blood vessels are visualized by hyperintense signals in STIR sequences and hypointense signals in T1-weighted sequences, and they appear mainly in the posterior part of the vertebral body (Fig. 117.14). A hemangioma (see Fig. 117.14) is defined as an accumulation of blood vessels typically located within the vertebral body. Although its MRI appearance is similar to that of inflammatory bone marrow edema, these findings represent physiologic abnormalities and not inflammatory changes. In contrast, the most important feature for the inflammatory differential diagnosis is the extension of the hyperintense signal into the surrounding soft tissue across anatomic borders, which is typical of bacterial spondylodiskitis. Finally, because of underlying osteoporosis in association with a rigid stiffness of the spine, an increase in the risk of spinal fractures has been reported in patients with established AS, especially in patients with long disease duration and a high

Fig. 117.12 Modic 1 lesion (arrows) characterized by bone marrow edema in the area of the vertebral endplates on short tau inversion recovery (STIR) magnetic resonance image and by hypointense signal on T1-weighted image, accompanied by a decrease in disk height and degeneration of the intervertebral disk.

Fig. 117.14 Magnetic resonance image showing blood vessels (thin arrows), appearing mainly in the posterior and middle part but also extending to the anterior part of the vertebral body, sometimes forming a hemangioma (thick arrow).

Fig. 117.13 Diffuse idiopathic skeletal hyperostosis (DISH) in the cervical spine as imaged by magnetic resonance imaging (a, b), conventional radiography (c), and computed tomography (d, e). DISH is characterized by bulky osteophytes that exceed the length of the anterior longitudinal ligament.

Fig. 117.15 Nondisplaced spinal fracture in the anterior part of the vertebral body. Because of the low bone mineral density, these fractures are not apparent on conventional radiographs (left panel). On magnetic resonance images (right panel), they are characterized by hyperintense signal on T1-weighted sequences with gadolinium diethylenetriamine-pentaacetic acid contrast (T1/Gd-DTPA) or short tau inversion recovery (STIR) sequences and by hypointense signal on T1-weighted sequences.

Fig. 117.16 Magnetic resonance images showing subarachnoid cysts, which are the pathophysiologic basis for the development of cauda equina syndrome, a rare but characteristic feature in patients with ankylosing spondylitis.

degree of spinal involvement.^{57,58} Spinal fractures in AS occur most frequently in the cervical spine^{59,60} but also may be seen in the cervicothoracic and thoracolumbar spine, often due to hyperextension injuries.^{54,61} Because of low bone mineral density and severe ankylosis, nondisplaced spinal fractures may not be diagnosed easily by conventional radiography (Fig. 117.15). The shear forces resulting from spinal movements may lead to dislocation of the injured spinal segment.⁵⁹ Spinal CT is necessary to diagnose a possible dislocation in patients with persistent or progressive symptoms after injury. Acute fractures show an increased signal intensity on STIR-weighted MRI and variable enhancement in T1/Gd-DTPA MRI, which indicates the location of the fracture line⁶² (see Fig. 117.15). On T1-weighted MRI the fractures display a decreased signal intensity⁶¹ (see Fig. 117.15). Finally, a disruption of the anterior longitudinal ligament is detected as a discontinuation and step-off of the low-signal-intensity structure along the anterior side of the vertebral body.⁶²

Cauda equina syndrome

Cauda equina syndrome (CES) is a rare but characteristic feature in patients with AS that occurs mainly in patients in advanced disease stages.⁶³ The pathophysiologic basis is cysts of the dural sack (Fig. 117.16). Clinically, these cysts may cause nerve compression symptoms such as irradiating pain

Fig. 117.17 Magnetic resonance images showing costochondritis (arrow) in a patient with ankylosing spondylitis.

and limb numbness. The ultimate cause of CES in AS is not completely known, but arachnoiditis due to inflammation of the posterior facet joints leading to adhesions within the thecal sac seems to be a likely explanation.⁶⁴ CES is characterized by slow and progressive sensorimotor loss possibly resulting in sphincter disturbances and incontinence. The overall prevalence of neurologic symptoms in AS patients is in the range of 2.1%,⁶⁵ and CES is not an infrequent cause of these.⁶⁶

Since diagnosis of CES by conventional radiographs is impossible, CT and MRI, which both are able to show enlargement of the caudal sac and the dorsal arachnoid diverticula, must be performed⁶⁷ (see Fig. 117.16).

IMAGING OF EXTRAVERTEBRAL MANIFESTATIONS OF AXIAL SPONDYLOARTHRITIS

Peripheral or extravertebral inflammatory manifestations of SpA may present clinically as involvement of the soft tissue (enthesitis, bursitis). However, when MRI is used, bone marrow edema (sympphysitis, costochondritis) may be found.

Involvement of the pubic symphysis may be seen in up to 25% of patients with axSpA. In most cases this is detected only in later stages of the disease when advanced abnormalities in the SIJ have already occurred.⁶⁸ In earlier stages of disease, symphysitis may be detected by MRI sequences sensitive for inflammation and appears as subcortical, anteriorly located bone marrow edema, indicating either enthesitis or pelvic instability, with a correspondingly decreased signal on T1-weighted sequences. However, involvement of the symphysis generally is not pathognomonic nor specific for a diagnosis of axSpA. Costochondritis (Fig. 117.17) is also a frequent extravertebral manifestation and can occur in up to 26% of axSpA patients.⁶⁹ Interestingly, many patients show no association between imaging assessments of

Fig. 117.18 Magnetic resonance image showing enthesitis (right arrow) and bursitis of the subachilleal bursa (left arrow) in a patient with peripheral spondyloarthritis.

costochondritis or anterior chest wall involvement and clinical signs of the disease.⁶⁹

Enthesitis (Fig. 117.18) and bursitis are clinical hallmarks of the spondyloarthritides. Frequently affected sites of enthesitis in SpA are the major trochanter, the pes anserinus, the Achilles tendon (see Fig. 117.18), and the retrocalcaneal bursa. Peripheral enthesitis may appear clinically as arthritis, but a differentiation can be achieved by MRI.⁷⁰ However, enthesitis is also well detected by ultrasonography.^{71,72} Both the longitudinal and the transversal axes need to be scanned to detect pathologic changes. In B mode (two-dimensional, real-time sequence), the presence of anechoic areas within the tendon sheath, especially in association with decreased echogenicity or synovial thickening, is considered to represent tenosynovitis.⁷³

Bursitis is seen as an enlarged bursa with a central hypoechoic zone.⁷³ Power Doppler ultrasonography is especially useful for visualization of vascularization at the cortical bone, the insertion of entheses, the junction between tendon and entheses, the body of tendons, and bursae. On ultrasonographic examination, most patients with SpA are found to have peripheral enthesitis, mostly in the distal portion of the lower limbs, irrespective of SpA subtype and other clinical symptoms.⁷² Inflammation of the tarsus⁷⁴ may occur as a first symptom earlier than manifestations at the axial skeleton and may develop into a chronic disease state characterized by ankylosis.⁴²

FUTURE PERSPECTIVES IN THE IMAGING OF SPONDYLOARTHRITIS

One important area of research in the field of imaging in spondyloarthritis is the potential of MRI to detect areas in the axial skeleton that will present any type of metabolic activity in order to predict those lesions which are going to show bone progression in the future. At the moment, more advanced techniques are being developed and tested in pilot studies, some of them also having the potential to be included in future research projects or maybe also in daily clinical routine. Preliminary studies with stronger MRI fields such as 3 Tesla MRI scanners or fusion imaging techniques such as positron emission tomography (PET)-CT and PET-MRI (Figure e117.1a and b) have shown that the sensitivity of the MRI scanners used in daily practice (1.0-1.5 Tesla) can be improved.⁷⁵ This suggestion is supported by studies analyzing biopsies of the facet joints⁷⁶ and the sacroiliac joints⁷⁷ of patients with clinical symptoms for SpA but negative MRIs, still showing areas with clear-cut inflammation detected histologically. The research on the diagnostic utility and clinical feasibility of such highly sensitive imaging techniques will lead to improved understanding of the processes underlying the development and the course of this disease but also lead the therapeutic research and clinical decisions in the future.

Management of ankylosing spondylitis/axial spondyloarthritis

■ JOACHIM SIEPER

- Early diagnosis, patient education, and physical therapy are essential for the successful management of ankylosing spondylitis (AS).
- The goals of physical therapy are to restore and maintain posture and movement to as nearly normal as possible.
- Self-management with exercises must be continued on a lifelong basis.
- Nonsteroidal antiinflammatory drugs (NSAIDs) and anti-tumor necrosis factor- α (anti-TNF- α) drugs are the only effective drugs available for the axial manifestations of AS.
- NSAIDs relieve pain and stiffness and facilitate physical therapy and might even be effective in preventing radiologic progression.
- Sulfasalazine and methotrexate have some effect on peripheral joint disease.
- Anti-TNF- α therapy is very effective in relieving symptoms and seems to have the potential for true disease modification.

HISTORICAL PERSPECTIVE

Until recently, rheumatologists have been much less interested in studying ankylosing spondylitis (AS) than other rheumatic diseases such as rheumatoid arthritis (RA) and lupus. This is despite the former's relatively high prevalence of between 0.2% and 1.0%¹ and the initial occurrence of symptoms early in life. The limitation of treatment options can probably be regarded as one important reason for this lack of interest.

The analgesic properties of salicylates and opioids led them to be among the first treatments that were offered to AS patients. Aspirin, a salicylate with less toxicity than salicylic acid, was developed in 1899. However, this drug was not as effective for AS as it was for other inflammatory rheumatic diseases. Beginning in the 1920s, radiation therapy was used to treat spinal inflammation with good results, including improvement of pain and stiffness. However, this type of treatment was discontinued once the serious long-term side effects such as leukemia and other hematologic malignancies became evident.

In 1949, phenylbutazone was introduced into clinical practice and showed very good efficacy in reducing pain and inflammation in patients with AS. It was the first drug for which the term *nonsteroidal antiinflammatory drug* (NSAID) was applied. However, because phenylbutazone causes serious side effects, notably aplastic anemia and hepatic injury, its use became restricted. It was largely replaced by indomethacin and, subsequently, other NSAIDs. Corticosteroids, despite being very effective in treating diseases such as RA, proved to be less effective for the treatment of AS.

The so-called disease-modifying antirheumatic drugs (DMARDs), including gold salts, antimalarial drugs, D-penicillamine, sulfasalazine, methotrexate, and various other immunosuppressive agents, were found to be effective for the treatment of RA but are either much less effective or not effective at all for the treatment of AS.

Current perspectives

The recently established efficacy of tumor necrosis factor (TNF)-blocking agents in treating patients with active AS, in contrast to the disappointing results from the agents just mentioned, has transformed treatment of this chronic inflammatory, frequently disabling disease.

Recently, an international group of experts from the Assessment of SpondyloArthritis international Society (ASAS) published recommendations for

the management of AS, which form part of the European League Against Rheumatism (EULAR) recommendations for various rheumatic diseases.² These recommendations are summarized in 11 bulleted statements in [Box 118.1](#) and in a flowchart in [Figure 118.1](#). It can easily be seen that NSAIDs and TNF blockers are regarded as the most important and possibly the only relevant part of the pharmacologic treatment that has to be combined with nonpharmacologic treatment during the entire course of the disease.

New classification criteria were published in 2009 for the entire group of axial spondyloarthritis (SpAs); the criteria apply not only to patients with AS and radiographic sacroiliitis according to the modified New York criteria³ but also to patients with nonradiographic axial SpA (nr-axSpA)—those in whom structural damage visible on radiographs has not yet developed⁴ (see also Chapter 113). These criteria allow clinical trials to be performed not only in AS patients but also in those with nr-axSpA only and the whole group of patients with axSpA.

ASSESSMENT OF EFFICACY OF TREATMENT OF ANKYLOSING SPONDYLITIS

To judge the efficacy of certain treatments, instruments for the measurement of improvement during therapy are needed, both for clinical trials and for daily clinical practice. In parallel with the limited effective pharmacologic therapies for AS, until recently there were only poorly defined tools available to assess outcome in clinical trials.

Pooled indices

Assessment of SpondyloArthritis international Society criteria

In 1995 the ASAS was formed and established a core set of domains and individual instruments for the evaluation of AS ([Table 118.1](#)).⁵ Subsequently, the ASAS developed criteria for the short-term improvement of AS patients treated with symptom-modifying drugs by analyzing treatment trials involving NSAIDs. According to these criteria, improvement in AS is defined as both relative improvement of at least 20% and actual improvement of at least 10 units on a scale of 0 to 100 in each of three domains, with no worsening in the fourth domain of more than either 20% or 10 units ([Table 118.2](#)). Partial remission was defined as a low level of disease activity below 20 units on a scale of 0 to 100 in each of the four domains (see [Table 118.2](#)).^{5,6} Once the dramatic therapeutic effects of TNF-blocking agents became evident, higher levels of response, such as ASAS40 improvement (see [Table 118.2](#)), were defined in these domains. In addition, ASAS5/6 criteria were proposed and based on a 20% improvement in at least five of six domains, including the same four domains defined in the ASAS20 criteria with the addition of acute-phase reactants and spinal mobility (see [Table 118.2](#)). Most recently, an AS Disease Activity Score has been developed by taking into account total back pain (Bath Ankylosing Spondylitis Disease Activity Index [BASDAI] question 2), patient global evaluation, peripheral joint pain or swelling (BASDAI question 3), duration of morning stiffness (BASDAI question 6), and C-reactive protein (CRP) (or erythrocyte sedimentation rate [ESR] if CRP is not available).⁵ This disease activity score differentiated better between responders and nonresponders in treatment trials than did the other scores.

Bath criteria

Apart from this ASAS core set, a number of measures of AS were developed by the Bath group in the United Kingdom. The BASDAI combined the level of pain in the spine, peripheral joints, and entheses, the level of fatigue, and the intensity and duration of morning stiffness and is frequently used as a

BOX 118.1 FIRST UPDATE OF THE ASAS/EULAR RECOMMENDATIONS FOR THE MANAGEMENT OF AS**Overarching principles of the management of AS**

- AS is a potentially severe disease with diverse manifestations that usually requires multidisciplinary treatment coordinated by a rheumatologist.
- The primary goal of treating patients with AS is to maximize long-term health-related quality of life through control of symptoms and inflammation, prevention of progressive structural damage, preservation or normalization of function, and social participation.
- Treatment of AS should aim at the best care and must be based on a shared decision between the patient and the rheumatologist.
- Optimal management of patients with AS requires a combination of nonpharmacologic and pharmacologic treatment modalities.

1. General treatment

Treatment of patients with AS should be tailored according to

- Current manifestations of the disease (axial, peripheral, enthesal, extraarticular symptoms and signs)
- Level of current symptoms, clinical findings, and prognostic indicators
- General clinical status (age, gender, comorbidity, concomitant medications, psychosocial factors)

2. Disease monitoring

Monitoring of disease in patients with AS should include

- Patient history (e.g., questionnaires)
- Clinical parameters
- Laboratory tests
- Imaging

All monitoring should be conducted according to the clinical findings, as well as the ASAS core set. The frequency of monitoring should be decided on an individual basis depending on the

- Course of symptoms
- Severity
- Treatment

3. Nonpharmacologic treatment

- The cornerstone of nonpharmacologic treatment of patients with AS is patient education and regular exercise.
- Home exercises are effective. Physical therapy with supervised exercises, land or water based and individually or in a group, should be preferred because these are more effective than home exercises.
- Patient associations and self-help groups may be useful.

4. Extraarticular manifestations and comorbid conditions

- Frequently observed extraarticular manifestations, such as psoriasis, uveitis, and IBD, should be managed in collaboration with the respective specialists.
- Rheumatologists should be aware of the increased risk for cardiovascular disease and osteoporosis.

5. Nonsteroidal antiinflammatory drugs

- NSAIDs, including coxibs, are recommended as first-line drug treatment for AS patients with pain and stiffness.
- Continuous treatment with NSAIDs is preferred for patients with persistently active, symptomatic disease.
- Cardiovascular, gastrointestinal, and renal risks should be taken into account when prescribing NSAIDs.

6. Analgesics

- Analgesics, such as paracetamol and opioid (like) drugs, might be considered for residual pain after previously recommended treatments have failed, are contraindicated, or are poorly tolerated.

7. Glucocorticoids

- Corticosteroid injections directed to the local site of musculoskeletal inflammation may be considered.
- The use of systemic glucocorticoids for axial disease is not supported by evidence.

8. Disease-modifying antirheumatic drugs

- There is no evidence for the efficacy of DMARDs, including sulfasalazine and methotrexate, in the treatment of axial disease.
- Sulfasalazine may be considered in patients with peripheral arthritis.

9. Anti-tumor necrosis factor therapy

- Anti-TNF therapy should be given to patients with persistently high disease activity despite conventional treatments according to the ASAS recommendations.
- There is no evidence to support the obligatory use of DMARDs before or concomitant with anti-TNF therapy in patients with axial disease.
- There is no evidence to support a difference in efficacy of the various TNF inhibitors in treating the axial and articular/enthesal disease manifestations, but in the presence of IBD a difference in gastrointestinal efficacy needs to be taken into account.
- Switching to a second TNF blocker might be beneficial, especially in patients with loss of response.
- There is no evidence to support the use of biologic agents other than TNF inhibitors for AS.

10. Surgery

- Total hip arthroplasty should be considered in patients with refractory pain or disability and radiographic evidence of structural damage, independent of age.
- Spinal corrective osteotomy may be considered in patients with severe disabling deformity.
- In patients with AS and an acute vertebral fracture, a spinal surgeon should be consulted.

11. Changes in disease course

- If a significant change in the course of the disease occurs, causes other than inflammation, such as a spinal fracture, should be considered and appropriate evaluation, including imaging, should be performed.

AS, ankylosing spondylitis; ASAS, Assessment of SpondyloArthritis international Society; DMARDs, disease-modifying antirheumatic drugs; EULAR, European League Against Rheumatism; IBD, inflammatory bowel disease; NSAIDs, nonsteroidal antiinflammatory drugs; TNF, tumor necrosis factor.

parameter of disease activity (Fig. 118.2).⁵ The Bath Ankylosing Spondylitis Function Index (BASFI), which is based on a questionnaire filled out by the patient, is the most frequently applied instrument for the measurement of function.⁵

Specific clinical and laboratory markers**Laboratory tests**

ESR and CRP values are lower in patients with AS than in those with RA, are elevated in only 50% to 60% of patients, and often do not correlate very well with disease activity. However, it was recently shown that elevated CRP is a risk factor for radiographic progression in both the sacroiliac (SI) joint⁶ and the spine.⁷

Spinal mobility

Limitation of spinal mobility and ankylosis of the spine are the major long-term adverse outcomes of AS, and any effective treatment should, besides improving the signs and symptoms, also be judged by its capacity to preserve spinal mobility and prevent or retard the occurrence of ankylosis in the spine. The Bath Ankylosing Spondylitis Metrology Index (BASMI) is a

combined tool for assessing spinal mobility and hip function. The BASMI 10 (Table 118.3) or the linear BASMI is recommended instead of the BASMI 3-point answer scale for clinical trials and in daily clinical practice because they are more sensitive to change.⁵ Measurement of chest expansion is often used as a stand-alone measure.

Imaging

In contrast to RA, for which radiographic change is an important endpoint and several validated scoring methods are available, radiographic change in AS is not a well-established measure of outcome. Only recently have scoring methods for radiologic change in the spine been evaluated. The best method currently seems to be the modified Stoke Ankylosing Spondylitis Spine Score (mSASSS), which has the highest reliability and the best sensitivity to change.⁵ This score ranges from 0 to 72 and scores 24 vertebral units (two opposing vertebral bodies of the anterior cervical and lumbar spine) as 0 (normal), 1 (erosion, sclerosis, or squaring), 2 (syndesmophyte), or 3 (bridging syndesmophyte).

In contrast to radiographic imaging, which may take several years to detect the consequences of inflammation (and not inflammation itself), magnetic resonance imaging (MRI) detects acute inflammation of the

ASAS/EULAR RECOMMENDATIONS FOR THE MANAGEMENT OF AS

Fig. 118.1 Flowchart summary of the Assessment of SpondyloArthritis international Society/European League Against Rheumatism (ASAS/EULAR) recommendations for the management of ankylosing spondylitis (AS). NSAIDs, nonsteroidal antiinflammatory drugs; TNF, tumor necrosis factor. (From Zochling J, van der Heijde D, Burgos-Vargas R, et al. Assessment in AS international working group: European League Against Rheumatism. ASAS/EULAR recommendations for the management of ankylosing spondylitis. *Ann Rheum Dis* 2006;65:442-52.)

TABLE 118.1

Assessment of disease in patients with ankylosing spondylitis

Domain	Instrument
Physical function	BASFI
Pain	VAS*—last week, spine, at night, attributable to AS; and VAS—last week, spine, attributable to AS
Spinal mobility	Chest expansion test, modified Schober test, and occiput-to-wall distance test
Patient global	VAS—last week
Stiffness	Duration of morning stiffness—spine, last week
Peripheral joints	Number of swollen joints (44-joint count)
Entheses	No preferred instruments yet available
Fatigue	First question of the BASDAI
Acute-phase reactants	ESR or CRP
Radiographs of spine and pelvis	Lateral lumbar spine, lateral cervical spine, and pelvis (sacroiliac and hip joints)

*Instead of a VAS (0 to 100), a numeric rating scale (0 to 10) can also be used and is easier to apply in daily clinical practice (see Fig. 118.2).

AS, ankylosing spondylitis; BASFI, Bath Ankylosing Spondylitis Function Index; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; VAS, visual analogue scale.

As proposed by the Assessment in Ankylosing Spondylitis (ASAS) Working Group and with modification from van der Heijde D, Bellamy N, Calin A, et al. Preliminary core sets for endpoints in ankylosing spondylitis. *Assessments in Ankylosing Spondylitis Working Group. J Rheumatol* 1997;74:4225-9.

entheses, bone, and synovium. Acute inflammation is best detected by applying contrast with gadolinium or diethylenetriamine pentaacetic acid (DTPA) or by using fat suppression techniques (i.e., short tau inversion recovery [STIR]). Scores for the quantification of acute lesions in the spine and SI joint have recently been proposed.⁸

PHYSICAL THERAPY

Physical therapy was for a long time the most important strategy in managing AS and remains the most important nonpharmacologic approach. Its aims are primarily to prevent or slow restriction of spinal mobility and the development of disability and also to improve the symptoms of pain and stiffness. Once the diagnosis of AS is made, the patient should be referred to a physical therapist to teach the patient the exercises to perform regularly.

TABLE 118.2

ASAS Working Group criteria for response*

A. Domains and instruments relevant for ASAS response criteria (4 domains)	
Patient global assessment	VAS (0-100)
Back pain	VAS (0-100)
Function	BASFI
Inflammation	Mean of duration and severity of morning stiffness (questions 5 and 6 of the BASDAI)
B. ASAS improvement criteria in 3 of 4 domains (on a scale of 0-100)	
ASAS20	≥20% and ≥10 units (on a scale of 0-100) in 3 of 4 domains with no worsening ≥20% and ≥10 units in the remaining domain
ASAS40	≥40% and ≥20 units with no worsening at all in the 4th domain
Partial remission	≤20 units (on a scale of 0-100) in all 4 domains
C. ASAS 5/6 improvement criteria: improvement (≥20%) in any 5 of the following 6 domains	
Patient global assessment	VAS (0-100)
Back pain	VAS (0-100)
Function	BASFI
Inflammation	Mean duration and severity of morning stiffness (questions 5 and 6 of the BASDAI)
C-reactive protein	
Spinal mobility	Measured by either spinal lumbar flexion or the BASMI (see Table 118.3)

*ASAS 20% (ASAS20) improvement and partial remission criteria have been developed based on NSAID studies.⁵ ASAS 40% improvement (highlighted in Fig. 118.3b) and 5 of 6 criteria (see Fig. 118.3c) differentiated best between placebo and drug response in anti-tumor necrosis factor- α trials.⁶ Instead of a VAS (0-100), a numeric rating scale (0-10) can also be used.

ASAS, Assessment of SpondyloArthritis international Society; BASFI, Bath Ankylosing Spondylitis Function Index; VAS, visual analogue scale.

Because the main long-term outcome to be prevented is flexion deformity of the spine, exercises concentrate on extension and rotation of the spine.² An exercise sequence for AS patients is shown in Figure 118.3.

Patients should be advised to exercise daily at home and to attend weekly group physical therapy sessions. The patient's own efforts are the key to future success, and patients have to be convinced that a daily exercise program should become a normal part of their day. In the long term many patients do not need to continue attendance, but some mechanism should exist to ensure that patients are seen and assessed regularly by their physical therapist. If patients are symptomatic and complain about pain or stiffness, they should also be treated with NSAIDs (see later) or other effective drugs to permit full mobilization during the exercises. Furthermore, patients should be encouraged to participate in moderate sport activities such as swimming and cycling.

Although the clear benefit of regular physical therapy has long been recognized at an individual level by patients and physicians, these impressions are supported by results from controlled trials. Thus in one study, a program combining physical therapy with patient education significantly improved function after 4 months in comparison to a control group.⁹ Another study comparing group physical therapy and daily home exercise with home exercise alone showed only a small advantage for group exercise.

Hydrotherapy might be of additional benefit in producing the appropriate environment in which movement can be maximized. Normal spa therapy seems to have at least as good a short-term effect as weekly group physical therapy plus daily home exercise, but its long-term effect is less certain.⁹ Other specific physiotherapy interventions such as pulsed shortwave, local ultrasound therapy, local heat or cold therapy, and transcutaneous nerve stimulation are used for the treatment of AS, but their additional potential value has not been well established.

Patient education is an essential part of nonpharmacologic therapy and should include information on pathogenesis, clinical manifestations, and course of the disease; information on physiotherapy (including advice about posture) and how to cope with the disease; and counseling on the socioeconomic consequences of the disease.²

BATH ANKYLOSING SPONDYLITIS DISEASE ACTIVITY INDEX (BASDAI)

Please tick the box which represents your answer (for example, ☒ 10).
All questions refer to **last week**.

1. How would you describe the overall level of fatigue/tiredness you have experienced?

☐ 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐ 6 ☐ 7 ☐ 8 ☐ 9 ☐ 10
none very severe

2. How would you describe the overall level of AS **neck, back, or hip** pain you have had?

☐ 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐ 6 ☐ 7 ☐ 8 ☐ 9 ☐ 10
none very severe

3. How would you describe the overall level of pain/swelling in joints **other than** the neck, back, or hips you have had?

☐ 0 ☐ 1 ☐ 2 ☐ 3 ☐ 4 ☐ 5 ☐ 6 ☐ 7 ☐ 8 ☐ 9 ☐ 10
none very severe

4. How would you describe the overall level of discomfort you have had from any areas tender to touch or pressure?

NONBIOLOGIC PHARMACOLOGIC THERAPY

Nonsteroidal antiinflammatory drugs

NSAIDs are regarded as the cornerstone of pharmacologic intervention for AS; they reduce pain and stiffness rapidly after 48 to 72 hours.

The first NSAIDs used for the treatment of AS were phenylbutazone and indomethacin, which were shown to be effective in controlled trials. Subsequently, many others have been shown to be effective, including diclofenac, naproxen, ibuprofen, piroxicam, meloxicam, ketoprofen, and aceclofenac, among others (Table 118.4).¹⁰⁻¹⁷ More recently, efficacy in treating AS has also been demonstrated for the cyclooxygenase-2 (COX-2)-selective

Fig. 118.3 An exercise sequence used in patients with ankylosing spondylitis. Cervical spine exercises include full extension (a) and rotation (b). A sequence of back extension (c and d) is followed by rotation in the lying (e and f) and upright kneeling (g) positions. Finally, breathing with the thoracic muscles is practiced (not shown).

TABLE 118.4

Overview of nonsteroidal antiinflammatory drugs that have been studied for treatment of ankylosing spondylitis

Drug	Half-life (hr)	Approved maximum daily dosage (normally for arthritis)	Investigated for ankylosing spondylitis	Efficacy for ankylosing spondylitis	Ref
Aceclofenac	4.0-4.3	200 mg	Aceclofenac 100 mg twice daily vs. tenoxicam 20 mg daily	Equally effective	10
Celecoxib	8-12	400 mg	Ketoprofen 100 mg twice daily vs. celecoxib 100 mg twice daily vs. placebo	Celecoxib and ketoprofen equally effective, both superior to placebo	11
Etoricoxib	≈22	90 mg	Etoricoxib 90 mg daily vs. etoricoxib 120 mg daily vs. naproxen 1000 mg daily vs. placebo	Etoricoxib in both dosages superior to naproxen, naproxen superior to placebo	12
Ibuprofen	1.8-3.5	2400 mg	Ketoprofen 100 mg twice daily vs. ibuprofen 400 mg three times daily	Ketoprofen superior to ibuprofen	13
Indomethacin	2	150 mg	Aceclofenac 200 mg daily vs. indomethacin 100 mg daily	Equally effective	14
Diclofenac	≈2	150 mg	Diclofenac 75, 100, 125 mg daily vs. indomethacin 75, 100, 125 mg daily	Equally effective	15
Ketoprofen	1.5-2.5	200 mg	Ketoprofen 100 mg twice daily vs. celecoxib 100 mg twice daily vs. placebo	Ketoprofen and celecoxib equally effective, both superior to placebo	11
Naproxen	10-18	1000 mg	Etoricoxib 90 mg daily vs. etoricoxib 120 mg daily vs. naproxen 1000 mg daily vs. placebo	Etoricoxib in both dosages superior to naproxen, naproxen superior to placebo	12
Meloxicam	≈20	15 mg	Piroxicam 20 mg daily vs. meloxicam 15 mg daily vs. meloxicam 22.5 mg daily vs. placebo	Equally effective in all 3 treatment groups, superior to placebo	16
Piroxicam	30-60	20 mg	Piroxicam 20 mg daily vs. meloxicam 15 mg daily vs. meloxicam 22.5 mg daily vs. placebo	Equally effective in all 3 treatment groups, superior to placebo	16
Phenylbutazone	50-100	600 mg	Flurbiprofen 200 mg 3 times daily vs. phenylbutazone 300 mg	Equally effective	17

Fig. 118.4 Percentage of patients with ankylosing spondylitis (AS) versus those with mechanical back pain who exhibit a good or very good clinical response to a full dose of a nonsteroidal antiinflammatory drug (NSAID). (Modified from Amor B et al.¹⁸)

inhibitors celecoxib and etoricoxib (see Table 118.4). When AS patients are asked about the level of efficacy when treated with NSAIDs, 70% to 80% report good or very good improvement in their symptoms.^{12,18} In contrast, this level of response is reported by only about 15% of patients with chronic low back pain of noninflammatory etiology (Fig. 118.4).¹⁸ Furthermore, a good response to NSAID treatment can be used as a helpful diagnostic approach to differentiate chronic back pain attributable to AS from other causes.¹⁸ Major improvement can occur with NSAIDs, with up to 15% of active AS patients treated with a full dose of an NSAID reaching the ASAS criteria for partial remission.¹⁸

In AS patients with active disease, the highest tolerated dose of a single NSAID might be necessary to achieve an optimal effect, although a dose plateau may be reached. Thus in a recent study, 120 mg/day of etoricoxib was not superior to 90 mg/day.¹² Normally, the optimal effect of an NSAID is reached in about 2 weeks, but sometimes a longer duration of treatment is necessary to determine the optimal dose. In some patients a full dosage

is needed to cover the entire day, whereas if morning stiffness and pain at night are the predominant symptoms, a long-acting nighttime dose might be sufficient. The treating physician should be familiar with the optimal dose of at least three different NSAIDs, such as diclofenac, indomethacin, and naproxen, and at least one coxib because patients often respond to one NSAID but not another.

A recent study in which different NSAIDs were compared for the treatment of AS found that the level of improvement was higher in AS patients with axial manifestations only than in AS patients with axial symptoms plus peripheral arthritis.¹⁹ The reason for this difference is unknown.

Nonsteroidal antiinflammatory drugs as disease modifiers

One interesting question is whether NSAIDs are effective only in reducing symptoms or whether they might have an additional effect on the long-term outcome of AS. One earlier study reported a reduction in spinal ossification after prolonged and continuous use of phenylbutazone in patients with AS.²⁰ Similar findings have been reported for treatment with indomethacin. The issue has therefore been raised whether NSAIDs should be given continuously or, in the light of their potential toxicity, should be administered only during disease flare-ups. A recent study allocated a total of 215 patients to receive treatment with NSAIDs either continuously or only on demand for a period of 2 years. All patients began treatment with celecoxib at a starting dosage of 100 mg twice daily; patients could increase the dosage to 200 mg twice daily or could change to another NSAID. Most interestingly, significantly less radiographic progression was found in the continuous-treatment group than in the on-demand group (Fig. 118.5),²¹ thus suggesting that NSAIDs may have disease-controlling properties. In this study no increased toxicity was noted in the continuous-treatment group. Intriguingly, the overall level of clinical disease activity was not clearly different between the groups during the 2-year treatment period. A subsequent analysis of the study showed that only patients with elevated acute-phase reactants (CRP, ESR, or both) benefited from continuous NSAID therapy, not patients with normal CRP.²² It was indeed recently confirmed in another AS cohort that radiographic progression was slowed in patients with elevated time-averaged CRP or the presence of syndesmophytes at baseline when treated with higher cumulative doses of NSAIDs over a 2-year period.²³ These data raise the question whether such a possible disease-controlling effect is due to the antiinflammatory action of these drugs or whether these agents have additional actions. Furthermore, treatment with NSAIDs caused a significant decrease in serum CRP levels, either in comparison to baseline²⁴ or in comparison to placebo-treated patients.²⁵ More data are needed to confirm these exciting findings and to address these questions.

Fig. 118.5 Patients from a previous placebo-controlled trial were randomized to receive continuous ($n = 111$) or on-demand ($n = 104$) treatment with celecoxib 2×100 mg/day, which could be increased to 2×200 mg/day or could be changed to another NSAID. Radiographs of the spine were scored at baseline and after 2 years of treatment according to the modified Stoke Ankylosing Spondylitis Spine Score (mSASSS) without information on the order of the films. Each symbol represents one single patient. The slower radiologic progression in the continuous than in the on-demand group was significant ($P = .002$). (From Wanders A et al,²¹ with permission from John Wiley & Sons, Inc.)

It still needs to be determined whether NSAIDs should be used continuously even if patients are free of symptoms.²⁶

A key factor is the known toxicity of NSAIDs, which must be taken into account when using such a treatment strategy. The toxicity of nonselective and COX-2-selective NSAIDs is now better understood than ever before. Severe gastrointestinal side effects can be expected in 1% to 3% of patients per year treated continuously with nonselective NSAIDs, whereas severe cardiovascular thrombotic side effects occur in 1% to 2% per year if either COX-2-selective inhibitors or traditional NSAIDs are chosen for treatment. These side effects are dose dependent and more frequent in patients with gastrointestinal or cardiovascular risk factors, respectively.²⁶

Patients who still have active disease despite treatment with NSAIDs or who do not tolerate such treatment should then be considered candidates for other therapies (see below).

Corticosteroids

Systemic corticosteroids

In contrast to other inflammatory rheumatic diseases such as RA, systemic corticosteroids do not play a major role in the treatment of AS.²⁷ This judgment is based on clinical experience because no studies have investigated the efficacy of oral corticosteroid therapy. Even though peripheral arthritis often improves if patients are treated with moderate doses of prednisolone (20 to 30 mg/day), the axial manifestations improve only slightly, if at all, at such a dose.

Some uncontrolled open trials and one double-blind randomized trial demonstrated good short-term efficacy of intravenous pulsed methylprednisolone (1 g/day for 3 days) in patients with AS refractory to therapy. However, there is no evidence of a long-term effect of such treatment.

Intraarticular corticosteroids

Intraarticular corticosteroid injections into the SI joints have been shown to be effective. Usually, 40 mg of triamcinolone is injected; intraarticular positioning of the needle should be guided by computed tomography (CT) (Fig. 118.6a) or, if available, by open low-field MRI. An improvement in symptoms and a reduction in inflammation as detected by MRI (see Fig.

118.6b and c) have been demonstrated for up to 6 months and sometimes even longer. Non-CT- or non-MRI-guided local injections of the SI joint (most of them probably periarticular) have also been reported to occasionally be effective, although no formal study is available. Local corticosteroid injections are likewise recommended for peripheral joint manifestations² and particularly for enthesitis.²⁸

Conventional disease-modifying antirheumatic drugs

In general, conventional DMARDs, which play such a dominant role in the treatment of RA, have no proven efficacy for the axial manifestations of AS and limited efficacy for the peripheral manifestations.

Sulfasalazine

Sulfasalazine is the best-investigated DMARD for the treatment of AS. A recent Cochrane review analyzed the published studies of AS.²⁹ The pooled analysis, based on 11 studies, showed that the difference between intervention groups was significant only for ESR and morning stiffness, with sulfasalazine favored over placebo, but not for the other variables. One trial investigating patients with a relative short disease duration (<6 years) showed a benefit in the primary outcome parameters, including back pain, spinal mobility, and well-being. Another reported no effect in patients with axSpA and a symptom duration of less than 5 years,³⁰ including patients with nr-axSpA.⁴ By contrast, several trials showed higher efficacy of sulfasalazine than placebo in patients with peripheral arthritis. Based on these results, sulfasalazine is not recommended for treatment of the axial manifestations of AS but may be used for peripheral arthritis in AS patients (see Box 118.1).² Normally, treatment at a dosage of 2 g/day, which can be increased to 3 g/day, for a duration of up to 4 months is necessary before treatment failure can be assumed.

Methotrexate

Given the efficacy of methotrexate for the treatment of RA, the lack of good studies of methotrexate for AS is surprising. Three randomized controlled trials have been published in which patients with AS were treated with methotrexate at a dosage of between 7.5 and 10 mg/wk versus placebo and a treatment duration of 12 to 24 weeks. Methotrexate was not superior to placebo in two of these studies. In the third study, a high percentage of patients in the methotrexate-treated group with concurrent peripheral arthritis had a better response in some of the outcome variables. In all three trials the subgroups were too small to differentiate between the effect in patients with axial manifestations only and the effect in those with additional peripheral arthritis. A more recent trial did not find any efficacy of 20 mg methotrexate given subcutaneously once a week for up to 16 weeks.³¹ Therefore, methotrexate is not recommended for either the axial or the peripheral manifestations of AS.

The lack of clear evidence of the efficacy of sulfasalazine and methotrexate for the treatment of AS contrasts with the fact that up to 20% to 30% of patients with AS are treated with one of these two drugs, probably because of the lack of alternative therapies.

Other disease-modifying antirheumatic drugs

There is no evidence that any of the other DMARDs often used for the treatment of RA play a role in the treatment of AS patients.²⁷ Recently, leflunomide was tested in two trials with negative results. In the first study, 20 AS patients were treated with 100 mg/day leflunomide for the first 3 days followed by 20 mg/day for 6 months. No change was observed in several of the outcome parameters, including the BASDAI. Only in a subgroup of 10 patients with peripheral arthritis was a decrease in the number of affected joints found.³² This beneficial effect restricted to peripheral arthritis was also shown in psoriatic arthritis. However, a larger number of patients would be necessary to confirm these results. In the second randomized controlled study, 45 patients with AS were treated with either the same dosage of leflunomide or placebo, also for 6 months, and no significant difference was shown between the two groups.³³ Again, the number of patients with peripheral arthritis in this study was too small to allow any further conclusions to be derived in this subgroup.

Thalidomide has also been tested for the treatment of AS patients in open uncontrolled trials, mainly because of its assumed anti-TNF- α potential. In the largest study, 30 patients with AS were treated with 200 mg thalidomide daily (increased slowly to reach this final dosage) given at night over a 12-month period. Twenty-six patients completed the study, with 80% showing at least 20% improvement in several variables starting after 3 to 6 months of therapy and 9 patients becoming free of symptoms. A similar result was reported by the same group in another smaller open study.

Fig. 118.6 Intraarticular corticosteroid injection into the sacroiliac joints. (a) Computed tomography-guided intraarticular injection of 40 mg triamcinolone acetonide. The tip of the needle (arrow) is located deep in the joint space. (b) Magnetic resonance imaging (MRI) of the sacroiliac (SI) joints (short tau inversion recovery [STIR] sequence) of a 37-year-old patient with ankylosing spondylitis shows osteitis at the left SI joint (arrows) before injection. A small intraosseous cyst is seen at the dorsal part of the iliac bone (arrow on bottom right). (c) MRI (STIR sequence) of the SIJs 4 months after the injection shows complete resolution of the osteitis. As expected, no change is seen at the intraosseous iliac cyst (arrow). (Courtesy K.G. Hermann, Berlin.)

However, the side effects, especially sedation, are thought to be considerable, which will probably prevent widespread use and the performance of controlled studies for this drug.

Pamidronate, a bisphosphonate, has been tested in patients with rheumatic diseases because of its possible antiinflammatory and inhibiting effect on osteoclasts. In a 6-month randomized controlled trial, 60 mg pamidronate given intravenously once a month was superior to a small placebo-like dosage of 10 mg pamidronate, with significant improvement being demonstrated in function and pain.³⁴ Such an effect became evident only after 3 months of treatment. A positive effect was not observed in another open trial in which AS patients were treated with the same dosage over a period of 3 months. Further studies are needed before bisphosphonates can be recommended.

Biologic Agents

Besides TNF- α inhibitors, other biologic agents have been investigated for the treatment of AS. The interleukin-1 (IL-1) receptor antagonist anakinra given as a 100-mg daily subcutaneous injection for 6 months did not show any efficacy in 20 active TNF blocker-naïve patients with AS in an open-label trial.³⁵ Abatacept (10 mg/kg) was administered intravenously on days 1, 15, and 29 and every 28 days thereafter up to week 24 to 15 TNF- α inhibitor-naïve patients and 15 with an inadequate response to TNF- α inhibitors; no clear improvement in signs and symptoms was noted in the two groups.³⁶ Similarly, the IL-6 receptor antagonist tocilizumab administered at a dose of 8 mg/kg body weight every 4 weeks over a 3-month

period was not superior to placebo in TNF blocker-naïve patients with active AS.³⁷ Interestingly, rituximab given as two 1000-mg infusions 2 weeks apart resulted in a clinically relevant improvement in a small-label study in TNF-naïve patients but not in those with active AS who failed TNF therapy.³⁸ However, this result needs to be further investigated in a placebo-controlled trial design. Thus, at the moment there is no clear evidence for a role of any other non-TNF blocker in the treatment of AS.

Anti-tumor necrosis factor- α blocking agents

The limited treatment options available for AS patients discussed earlier mean that the demonstration of good or very good efficacy of TNF blockers in treating active AS can be regarded as a breakthrough in the treatment of AS.² These drugs improve the signs and symptoms of AS rapidly in a high percentage of patients. Whether they are also capable of stopping structural damage of the bone, as has already been shown in RA, still has to be demonstrated.

Biologic basis

Inflammation at the interface of cartilage and bone has convincingly been demonstrated by MRI and immunohistologic techniques³⁹ in SI joint biopsy specimens. Abundant TNF- α mRNA has been found in the inflamed SI joint,³⁹ thus clearly demonstrating that AS is an inflammatory disorder. TNF- α is a proinflammatory cytokine produced by monocytes, macrophages, and activated T cells. TNF- α induces the release of other cytokines such as IL-1 and IL-6, as well as metalloproteinases and prostaglandins; it

is involved in the activation of lymphocytes, as well as in osteoclastogenesis. Furthermore, TNF- α induces the expression of endothelial adhesion molecules (e.g., E-selectin, intracellular adhesion molecule 1, and vascular adhesion molecule 1). Thus TNF- α plays a central role in inflammation.

Using enzyme-linked immunosorbent assays, elevated serum levels of TNF- α and IL-6 have been found in patients with AS.

Today, there are five main biologic agents that target TNF- α : the chimeric ($\frac{1}{4}$ murine and $\frac{3}{4}$ human) monoclonal IgG1 antibody infliximab, the recombinant 75-kDa TNF receptor IgG1 fusion protein etanercept, and the fully humanized monoclonal antibodies adalimumab and golimumab, and the PEGylated Fc-free anti-TNF certolizumab. All five TNF inhibitors have already been approved for the treatment of AS in the European Union, the United States, and other parts of the world. Infliximab is administered as an intravenous infusion over a 2-hour period, whereas etanercept, adalimumab, golimumab, and certolizumab are injected subcutaneously.

Infliximab

Short-term efficacy

Efficacy is based on the results of two pivotal placebo-controlled, randomized controlled trials in which infliximab was administered intravenously at a dosage of 5 mg/kg body weight at weeks 0, 2, and 6 and thereafter every 6 to 8 weeks. In contrast to treatment of RA, infliximab was given in both studies as monotherapy without concomitant treatment with DMARDs or corticosteroids.

In the first study, patients were treated with either infliximab ($n = 34$) or placebo ($n = 35$) for 3 months.⁴⁰ After this time all patients were treated with infliximab and monitored long-term. In the second study, which used the same dosage and treatment intervals, 201 patients were treated with infliximab and 78 with placebo for 6 months.⁴¹ Patients had to have a BASDAI score of 4 or higher despite treatment with NSAIDs. Continuation of NSAID therapy was permitted in both studies. The crucial endpoint in both these studies was a 50% improvement in disease activity (BASDAI) (see Fig. 118.2) or in a composite clinical score (ASAS percent improvement; see Table 118.2).⁵ This endpoint was reached by about 50% of infliximab-treated patients in the placebo-controlled trials, with about 10% or less of the placebo group attaining this level of response (Fig. 118.7). This endpoint was also reached in up to 60% to 70% of patients in the open-label studies. Interestingly, between 20% and 25% of these patients with active AS even fulfilled the criteria for partial remission. In addition, the number of entheses sites, the number of affected peripheral joints, function, and spinal mobility improved (some reaching statistical significance) during the placebo-controlled phase.

Long-term efficacy

In the German randomized controlled trial,⁴⁰ 69 patients were treated continuously with infliximab for 3 years, with the same dose given every 6 weeks. After 54 weeks, 78% of the patients were still being treated; after 2 years, 70%; and after 3 years, 69%. The intention-to-treat primary efficacy analysis at week 54 showed that almost 50% of the patients achieved a 50% improvement in disease activity (BASDAI score). In the completer analysis, the pretreatment mean BASDAI score of 6.5 decreased further from 3.3 at week 12 to as low as 2.5 at week 54 and remained low until week 156. NSAIDs could be reduced in 70% of patients and discontinued in 59%.

When infliximab was discontinued after 3 years of therapy, patients experienced a relapse between weeks 7 and 45, and by week 52 all but one patient had active disease. When treatment with infliximab was begun again, all except one patient responded similar to the first time, and the drug was well tolerated. Thus, for this group of patients with very active, long-standing disease (mean disease duration >10 years), infliximab needs to be administered long-term. After 8 years of treatment, 48% of the initial patients were still taking the drug, with a similar level of improvement in the completers.⁴²

In the Ankylosing Spondylitis Study for the Evaluation of Recombinant Infliximab Therapy (ASSERT) study, 166 of the initial 201 patients were still taking infliximab after 2 years of treatment, with a continuously good response (Fig. 118.8).

Combination treatment with infliximab and methotrexate or other disease-modifying drugs

Reports of the treatment of RA and Crohn disease suggest that combining infliximab with methotrexate, glucocorticoids, or another immunosuppressive agent such as azathioprine (mostly for Crohn disease) might reduce side effects such as allergic reactions. However, two randomized controlled trials could not find a significant difference in efficacy or side effects in AS patients treated with infliximab alone or with a combination of infliximab and methotrexate.

Fig. 118.7 Assessment of SpondyloArthritis international Society 40% (ASAS40) response after 24 weeks of treatment of ankylosing spondylitis patients with (left to right): (1) infliximab, (2) etanercept, (3) adalimumab, or (4) golimumab. (Data from [1] van der Heijde D et al.⁴¹; [2] Davis JC, van der Heijde DM, Braun J, et al. Sustained durability and tolerability of etanercept in ankylosing spondylitis for 96 weeks. *Ann Rheum Dis* 2005;64:1557-62; [3] van der Heijde D et al.⁴⁸ with permission from ASAS [www.asas-group.org]; and [4] Inman, et al.⁵¹)

Impact of infliximab on active inflammation as seen on magnetic resonance imaging

MRI has proved to be a powerful tool for detection of acute inflammation in the SI joints and spine. Therefore, MRI should also be used for follow-up of these inflammatory lesions during treatment since it provides an objective outcome parameter for efficacy of a given therapy. Serial MRI studies performed in patients from the German randomized controlled trial demonstrated that after 3 months of treatment, active inflammatory lesions in the spine regressed significantly by 60% versus 20% deterioration in the placebo group.²³ As mentioned earlier, these patients from both groups were then treated in open-label studies continuously for up to 3 years. When MRI data at baseline and after 2 years of continuous treatment were analyzed, a persistent improvement in spinal inflammation was seen (Fig. 118.9), with a mean score for acute spinal lesions of 4.6 versus 15.2 at baseline. Data are also available from the other placebo-controlled trial⁴³ and showed a significant reduction in spinal inflammation but no reduction in the placebo group.

Etanercept

Short-term efficacy

Four double-blind placebo-controlled trials have been published that demonstrate the efficacy of etanercept in treating AS to be similar to that with infliximab. In the first study, 40 patients were treated with either etanercept 25 mg subcutaneously twice per week (20 patients) or placebo (20 patients). DMARDs and corticosteroids were allowed to be continued during the study in 40% and 25% of patients, respectively. The main outcome parameters of morning stiffness and nocturnal spinal pain improved significantly in the etanercept but not in the placebo group after 4 months of treatment. In a second single-center trial, 30 AS patients with active disease (BASDAI score ≥ 4) were randomized to therapy with etanercept or an initial

LONG-TERM (2-YEAR) EFFICACY OF THE TNF- α ANTAGONISTS IN PATIENTS WITH ANKYLOSING SPONDYLITIS*

*Different studies, no head-to-head comparison

Fig. 118.8 Long-term (2-year) efficacy of tumor necrosis factor- α (TNF- α) antagonists (infliximab [1], etanercept [2], and adalimumab [3]) in patients with ankylosing spondylitis. (Data from [1] Braun J, Deodhar A, Dijkmans B, et al. Efficacy and safety of infliximab in patients with ankylosing spondylitis over a two-year period. *Arthritis Rheum* 2008;59:1270-8; [2] Davis JC, van der Heijde DM, Braun J, et al. Sustained durability and tolerability of etanercept in ankylosing spondylitis for 96 weeks. *Ann Rheum Dis* 2005;64:1557-62; and [3] van der Heijde D, Schiff MH, Sieper J, et al. Adalimumab effectiveness for the treatment of ankylosing spondylitis is maintained for up to 2 years: long-term results from the ATLAS trial. *Ann Rheum Dis* 2009;68:922-9, with permission from ASAS [www.asas-group.org].)

placebo-controlled period of 6 weeks, followed by an observational phase lasting 24 weeks. The placebo group was switched to etanercept after 6 weeks, and both groups were treated with etanercept for 3 months. Treatment with etanercept was significantly better than placebo, with at least 50% regression of disease activity in 57% of these patients at week 6 versus only 6% in the placebo group. No severe adverse events, including major infections, were observed during this trial.

Subsequently, two further placebo-controlled international trials were performed with the same dosage of etanercept. In the first, 277 patients were treated with either etanercept ($n = 138$) or placebo ($n = 139$) for 24 weeks.⁴⁴ An ASAS50 response was seen at week 24 in 45% of the etanercept group versus 10% of the placebo group (see Fig. 118.7). In a second study consisting of 84 patients, very similar results were obtained.

Long-term efficacy

To date, three studies have been published with long-term follow-up data from the original randomized controlled trials. In one of the studies, 277 patients were enrolled over a 24-week period, and subsequently all were treated with etanercept and observed in an open-label extension trial for a further 72 weeks. After 2 years, 200 of the patients (72%) were still being treated with the drug. Fifty percent of patients showed an ASAS50 response at week 48, and 54% of the patients reached this level of response at week 96 (see Fig. 118.8). Recently, a 4-year follow-up of this study reported similar safety and efficacy over this period. The other long-term trial was a 2-year open-label extension study of another randomized controlled trial.⁴⁴ Overall, 21 of 30 patients (70%) completed year 2. In the intention-to-treat analysis, 54% of the patients were BASDAI 50% responders. In the completer analysis, 43% (9 of 21 patients) fulfilled the ASAS criteria for partial remission. The BASDAI score decreased from 6.3 at baseline to 2.7 after 1 year and 2.6 after 2 years. However, when treatment with etanercept was stopped after 3 months, relapse occurred at a mean of 6.2 ± 3 weeks, and at week 35 all 30 patients had relapsed. However, when treatment was started again, the response rate was similar to that at the initial treatment.

A 63% drug survival rate was reported in another study after 5 years of treatment of AS patients with etanercept.⁴⁵

Impact of etanercept on active inflammation as seen on magnetic resonance imaging

MRI results during treatment were also reported in two of these studies. In the larger study, MRI of the spine was available at baseline and weeks 12, 24, and 48.⁴⁶ After 12 weeks spinal inflammation regressed by 54% in the etanercept group but worsened by 13% in the placebo group. After switching to etanercept, placebo patients improved similarly. In the second study, significant regression of spinal inflammation was already seen after 6 weeks in patients treated with etanercept but not in patients given placebo. Continuous treatment with etanercept for 24 weeks resulted in a 69% reduction in active spinal changes, as well as a reduction of inflammation in the SI joints.⁴⁷

Adalimumab

Short-term efficacy

Adalimumab 40 mg subcutaneously given as monotherapy every other week for 52 weeks was first shown to be effective in 15 patients with active AS in an open-label trial. This effectiveness was subsequently confirmed in two placebo-controlled randomized trials. In the Adalimumab Trial Evaluating Long-Term Efficacy and Safety in AS (ATLAS) trial, 58.2% (121 of 208) of adalimumab-treated patients achieved an ASAS20 response as compared with 20.6% (22 of 107) in the placebo group at week 12. A BASDAI 50 response was reached by 45.2% of the patients in the adalimumab group versus 15.9% in the placebo group (see Fig. 118.7).⁴⁸

Long-term efficacy

In the ATLAS trial, 65% (202 patients) of the original 311 patients still participated in the trial at year 5.⁴⁹ The level of response was maintained over the 5 years of treatment; 70%, 77%, and 51% of the completers achieved ASAS40, BASDAI 50, and ASAS partial remission, respectively (see also Fig. 118.8 for the 2-year data).

Impact of adalimumab on active inflammation as seen on magnetic resonance imaging

Acute inflammation decreased in both the spine and SI joints as detected on MRI in the open-label trial. In one of the placebo-controlled trials, active inflammation of the spine and the SI joints, as shown on MRI, was scored at weeks 12 and 52. The applied score for the spine increased by 9.4% in the placebo group versus a mean decrease of 53.6% in the adalimumab-treated patients. Similarly, the SI joint score decreased by a mean of 12.7%

Fig. 118.9 Reduction of acute spinal inflammation as seen on magnetic resonance imaging (short tau inversion recovery technique) during infliximab treatment over a period of 2 years. No change in acute inflammation versus baseline (a) could be seen after 12 weeks (b) of treatment with placebo; however, inflammation disappeared after 2 years (c). (From Sieper J, Baraliakos X, Listing J, et al. Persistent reduction of spinal inflammation as assessed by magnetic resonance imaging in patients with ankylosing spondylitis after 2 yrs of treatment with the anti-tumour necrosis factor agent infliximab. *Rheumatology [Oxford]* 2005;44:1525-30.)

in the placebo group but by 52.9% in adalimumab-treated patients. This response was maintained at week 52 in the adalimumab group and reached a similar level of reduction after the placebo group was switched to adalimumab at week 12.⁵⁰

Golimumab

Golimumab, another fully humanized monoclonal antibody against TNF- α , is administered subcutaneously every 4 weeks. It showed good efficacy in a randomized placebo-controlled trial over a 24-week period,⁵¹ comparable to the other TNF-blocking agents.

Certolizumab

Certolizumab, a PEGylated Fc-free anti-TNF, is administered subcutaneously in doses of 200 mg every 2 weeks or 400 mg once every 4 weeks. It showed good efficacy in a randomized, placebo-controlled trial over a 24-week period in patients with axial spondyloarthritis, including a subgroup of patients with ankylosing spondylitis.^{51a}

Treatment of nonradiographic axial spondyloarthritis with tumor necrosis factor blockers

The AS patients treated in all the TNF blocker trials had a mean disease duration of longer than 10 years, which can be explained partly by the fact that the presence of radiographic sacroiliitis was a necessary inclusion criterion. Several studies have now been performed with TNF blockers either in the entire group of patients with axSpA or in patients with nr-axSpA only. To date, five controlled TNF blocker trials have been published. In all studies patients either retrospectively or prospectively fulfilled the new ASAS classification criteria for axSpA. In the first study, patients with nr-axSpA were treated with adalimumab or with placebo for 12 weeks; all patients were then switched to adalimumab and treated until week 52.⁵² An ASAS40 response was reached by 54.5% of patients in the adalimumab group versus 12.5% in the placebo group, efficacy being similar to that in the AS trials. The mean symptom duration in this trial was 7 to 8 years; patients with a shorter duration of symptoms had a better response than did patients with a longer duration. In another trial, patients with axSpA were included only if the duration of symptoms was less than 3 years, if patients showed active inflammation of the SI joints on MRI, if they were positive for HLA-B27, and if they suffered from the clinical symptom of inflammatory back pain.⁵³ Only about 12% of these patients also had radiographic evidence of sacroiliitis and fulfilled the modified New York criteria. More

than half the patients (55.6%) reached the ASAS criteria of partial remission versus only 12.5% in the placebo group. Active inflammation as seen on MRI improved significantly better in the infliximab-treated than in the placebo-treated group. In the third trial, patients with axSpA and a symptom duration of less than 5 years were treated in a randomized prospective trial for 1 year with either etanercept or sulfasalazine.⁸ A significantly higher number of patients in the etanercept group showed improvement in active subchondral bone marrow inflammation in the SI joints, the spine, and the peripheral entheses on whole-body MRI. Furthermore, 50% of the patients reached the ASAS criteria for partial remission in the etanercept group versus 19% in the sulfasalazine group after 1 year of treatment. Fifty-one percent of these patients had radiographic sacroiliitis at inclusion in the trial; the treatment effect was very similar in patients with nonradiographic and radiographic sacroiliitis.⁸ A phase 3 placebo-controlled trial of adalimumab in patients with nr-axSpA resulted in an ASAS40 response in 36.3% of the adalimumab-treated patients versus 14.9% of the placebo group.⁵⁴ Disease duration was rather long at a mean of 10 years, and patients in whom the duration of symptoms was less than 5 years had a better ASAS40 response, with 49% reaching the criteria for response. Finally, certolizumab showed a good efficacy for the treatment of nonradiographic axial SpA in a placebo-controlled 24-week trial, similar to the efficacy shown for the AS subgroup in the same trial.^{51a} Thus patients with nr-axSpA have an at least a similar response to TNF blocker treatment as do patients fulfilling the modified New York criteria for AS.

Currently, adalimumab and certolizumab are the first TNF blockers approved by the European Medicines Agency for patients with active nr-axSpA who either have an elevated CRP or active inflammation of the SI joint or spine on MRI.

Can radiographic damage or progression be prevented by tumor necrosis factor blocker treatment?

When radiographs of the spine were scored for growth of syndesmophytes over a follow-up period of 2 years, it was shown that all four TNF blockers—etanercept,⁵⁵ infliximab, adalimumab, and golimumab—did not stop radiographic progression over a treatment period of 2 years in comparison to a historical control group of AS patients not treated with TNF blockers. This raises the question of how inflammation and new bone formation are linked in AS. Based on an analysis of the available histologic and imaging literature, it was proposed that the structural damage in AS occurs in two steps.⁵⁶ First, inflammation causes erosive structural damage that results in bony defects

being filled with fibrous repair tissue. This would not be that much different from RA. Second, the repair tissue becomes ossified, which is made easier if inflammation is no longer present. This is probably typical for any damage in the spine. Thus, if inflammation is treated early enough before structural damage has occurred, TNF blockers might prevent new bone formation in the long term. However, TNF blockers will not prevent ossification of already damaged bone because these agents do not have an effect on osteoblast activity. Future studies need to show whether this assumption about the sequence of events is correct.

Tumor necrosis factor blockers for peripheral arthritis and enthesitis

Peripheral arthritis and enthesitis are frequent manifestations that are also characteristic of the whole group of SpAs and occur in 30% to 40% of patients with AS,⁴ normally in transient or relapsing form (or both), but chronic manifestations are also possible. TNF blockers have thus far been investigated mostly in studies addressing improvement in these peripheral manifestations as secondary outcome parameters. Both peripheral arthritis and enthesitis improved when patients were treated with TNF blockers in these studies. Enthesitis of the heel was the primary outcome measure in one placebo-controlled, 12-week trial of etanercept in patients with peripheral SpA, with significantly better improvement being shown in the etanercept group.⁵⁷

Tumor necrosis factor blockers for the treatment of psoriasis and inflammatory bowel disease in patients with ankylosing spondylitis

Psoriasis is present in about 10% and inflammatory bowel disease (Crohn disease or ulcerative colitis) in about 5% of patients with AS. Thus a relevant question is how these diseases are affected by treatment with TNF blockers. Most data available are derived from studies that have tested infliximab, etanercept, or adalimumab for the treatment of psoriasis or psoriatic arthritis (see also Chapter 122) and Crohn disease. All TNF blockers are effective for the treatment of psoriasis.

In Crohn disease, infliximab and adalimumab were shown to be highly effective for different manifestations of active disease, whereas etanercept failed to be superior to placebo in a controlled trial. There were even single reports of flares or new manifestations of Crohn disease in AS patients treated with etanercept. Infliximab and adalimumab are also effective for ulcerative colitis. Infliximab was more effective in preventing flares of inflammatory bowel disease in AS patients treated with TNF blockers than were adalimumab, etanercept, and placebo in an analysis of all published AS studies.⁵⁸

Tumor necrosis factor blockers for the treatment of juvenile spondyloarthritis

The first symptoms of AS occur in 15% to 20% of patients before the age of 20 years and in a considerable number of patients even 16 years or younger. Although juvenile forms normally occur initially with a predominance of peripheral manifestations (enthesitis and peripheral arthritis), the full picture of typical AS develops later in many juvenile patients. In two small open-label studies both infliximab and etanercept showed good efficacy in patients with juvenile SpA or enthesitis-related arthritis. One recent double-blind placebo-controlled trial showed highly significant improvement in a variety of clinical parameters in the infliximab-treated group in comparison to the placebo group.

Adverse events associated with anti-tumor necrosis factor therapy

Adverse events in AS patients treated with TNF blockers do not differ from those seen in patients with other diseases such as RA and Crohn disease. However, patients with AS are normally younger than those with the other two diseases and less frequently have been treated with glucocorticoids or immunosuppressive drugs. Thus the number and severity of side effects can be expected to be at least no higher than in other chronic inflammatory diseases and might even be lower. Comparative data on this issue are not available at this time. However, implementation of the usual precautions for and contraindications to biologic therapy should be followed. Infections, including opportunistic infections, can occur in a small percentage of patients, and a small increase in risk for the development of lymphoproliferative disorders cannot be excluded at this stage. Allergic reactions occur, and neurologic events and congestive heart failure have been reported occasionally.

Which patients with ankylosing spondylitis should be treated with tumor necrosis factor blockers?

Recommendations on which AS patients should be treated with TNF blockers are required, especially on the background of possible side effects and the relatively high cost of these drugs. Thus patients with the best

ASAS RECOMMENDATIONS FOR THE START OF TREATMENT OF AXIAL SPONDYLOARTHRITIS PATIENTS WITH TNF BLOCKERS

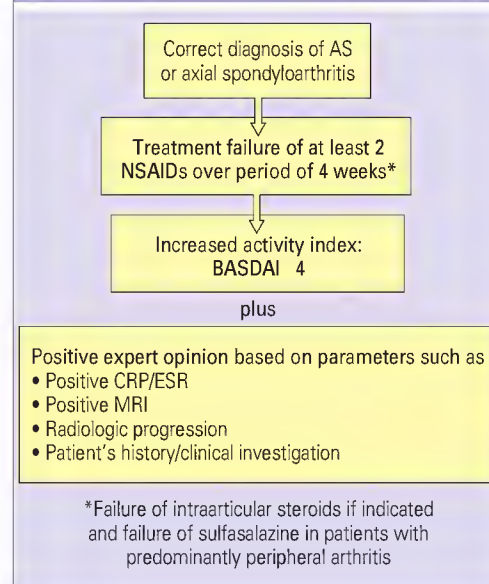

Fig. 118.10 Assessment of SpondyloArthritis international Society (ASAS) recommendations for the start of treatment of axial spondyloarthritis patients with tumor necrosis factor (TNF) blockers.⁵⁹ BASDAI, Bath Ankylosing Spondylitis Disease Activity Index; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal antiinflammatory drugs.

benefit-to-risk ratio should be treated preferentially. An international ASAS consensus statement on the use of anti-TNF agents in AS patients was just recently updated⁵⁹ (Fig. 118.10). According to these recommendations, the following criteria should be fulfilled for the initiation of anti-TNF- α therapy:

1. A diagnosis of axSpA made by fulfilling either the modified New York criteria for AS³ or the ASAS criteria for axSpA.⁴
2. The presence of active disease for at least 4 weeks as defined by both a sustained BASDAI score of at least 4 (on a scale of 0 to 10) and an expert opinion based on clinical features, acute-phase reactants, and imaging modalities. The expert will normally be a rheumatologist, and in addition to the patient's symptoms, the rheumatologist will make a judgment by taking into account the objective parameters of activity or inflammation.
3. The presence of refractory disease as defined by the failure of at least two NSAIDs during a 4-week period, failure of intraarticular corticosteroids if indicated, and failure of one DMARD, preferably sulfasalazine, in patients with peripheral arthritis. These recommendations are also in accordance with the ASAS/EULAR recommendations for the management of AS,³ which do not see a role for DMARDs in treating the predominant axial manifestations of AS (see Box 118.1 and Fig. 118.1).
4. The usual precautions for and contraindications to biologic therapy should be applied.
5. For monitoring of anti-TNF- α therapy, both the BASDAI and the ASAS core set for clinical practice should be followed regularly. Discontinuation of anti-TNF- α therapy should be considered strongly in nonresponders after 12 weeks of treatment (Fig. 118.11). Response is defined as improvement of at least 50% or 2 units (on a 0 to 10 scale) of the BASDAI in addition to an expert opinion that treatment should be continued, again not only relying on the patient's subjective symptoms.

Similar recommendations have been published by national societies such as the Canadian Rheumatology Association and the British Society of Rheumatology and from the United States; they follow the reasoning of the ASAS recommendations with only slight modifications.

Can a good response to tumor necrosis factor blockers be predicted?

The good results in axSpA patients treated with TNF blockers early in their disease raised the question of whether a shorter symptom duration is a

Fig. 118.11 Assessment of SpondyloArthritis international Society ASAS recommendations for when treatment of ankylosing spondylitis (AS) patients with tumor necrosis factor (TNF) blockers should be continued. If these criteria are not met, discontinuation should be considered.⁵⁹ BASDAI, Bath Ankylosing Spondylitis Disease Activity Index.

Fig. 118.12 Prediction of a major response, defined as Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) 50% improvement in patients with ankylosing spondylitis (AS) ($n = 99$) treated with tumor necrosis factor (TNF) blockers. The response of AS patients treated with TNF blockers is shown in correlation to disease duration (a) or the level of C-reactive protein (CRP) (b) at baseline. A short disease duration and high CRP predict a good response. (a, from Rudwaleit M et al,⁶⁰ with permission from the BMJ Publishing Group; b, modified from the same source.)

prognostic factor for a good treatment response for the entire group of axSpA patients, including those with AS. Based on analysis of the early AS trials it was shown that a symptom duration of less than 10 years was associated with a better response to TNF blocker therapy than was a longer duration of disease⁶⁰ (Fig. 118.12). Indeed, such an association was also found in the two adalimumab trials in patients with nr-axSpA, for which symptom duration was not limited.^{52,54} There was always a large overlap between short symptom duration and young age as predictors of a good treatment response. In one AS trial of adalimumab, 50% of patients reached ASAS partial remission if younger than 30 years as opposed to 39% of patients between 30 and

39 years of age and about 18% older than 40 years. In the first trial of adalimumab for patients with nr-axSpA, 87% reached the ASAS40 criteria if they were 30 years or younger versus only 16.7% if older than 40.⁵² Such a better response in patients with a shorter duration of disease was also confirmed in the second adalimumab study in patients with nr-axSpA.⁵⁴ The second predictor of a good response in nearly all analyses was an elevated CRP level at inclusion. Positive HLA-B27, active bony inflammation on MRI, and good function were not consistently associated with a favorable treatment response. Thus, patients with younger age, a short disease duration, or objective signs of inflammation—elevated CRP seems to be a better predictor than active inflammation on MRI—do respond especially well to TNF blocker therapy.

These analyses were based on the presence or absence of predictive factors at baseline. A more recent analysis of a 5-year follow-up of AS patients treated with adalimumab looked for parameters predicting sustained remission over several time points or predictors of the presence of remission after 5 years.⁴⁹ Besides baseline parameters, the response after 12 weeks was also taken into account. The best predictor was achieving remission at week 12. Taken together, an elevated CRP, short duration of symptoms, and good response to a TNF blocker in the first 3 months seem to be the best predictors of long-term response to TNF blocker therapy in patients with axSpA.

Switching from one tumor necrosis factor blocker to another in case of treatment failure

In patients with primary or secondary failure of treatment with a TNF blocker, switching to another can be effective, although the response rate is lower. In one study, an ASAS40 response was found in 38% of patients versus 59% of those with no previous exposure to TNF blockers. Patients respond better if the response is lost over time (secondary failure) than if they have no response to the initial course of treatment. In another report, a decrease in the BASDAI score by 2 points was still observed in patients who switched to a second and third TNF blocker, as opposed to a decrease of 3 BASDAI points in patients treated with their first TNF blocker. Secondary failure of treatment with a TNF blocker might be due to the induction of antidrug antibodies, which can occur in AS patients treated with TNF blockers, especially if treated with the monoclonal antibodies.

MANAGEMENT OF EXTRAARTICULAR MANIFESTATIONS

Anterior uveitis

Anterior uveitis is the most frequently occurring extraspinal manifestation in AS patients, with 30% to 40% experiencing isolated or recurrent attacks. It is typically unilateral, but relapses frequently affect the contralateral eye. Patients should seek immediate medical help if a painful eye occurs to avoid the formation of synechiae (adhesions to the back of the iris) with the possible consequence of secondary glaucoma. Local treatment with glucocorticoid eye drops and mydriatics is sufficient in most instances. In more severe cases, glucocorticoids given either orally or as an intraocular injection might be necessary. Results from controlled trials suggest that sulfasalazine can prevent attacks.

Experience in the treatment of anterior uveitis with TNF blockers is currently limited. In one study, 16 patients, 14 of whom received etanercept and 2 infliximab for either inflammatory eye disease or associated joint disease, were studied retrospectively. Although all 12 patients with active arthritis showed improvement in joint disease, only 6 (38%) experienced improvement in their eye disease. Inflammatory eye disease even developed for the first time in five patients while taking etanercept. Therefore, conclusions from this report regarding AS-associated uveitis are limited.

A beneficial effect of infliximab administered in a single dose of 10 mg/kg was reported in seven patients with an acute onset of HLA-B27-associated anterior uveitis. These patients were monitored for a mean period of 17 months. Total resolution of anterior uveitis was achieved with infliximab as the only antiinflammatory drug in all but one patient. Relapse occurred in four patients after a median of 5 months.

Recently, data from four placebo-controlled trials of TNF blockers for the treatment of AS (two with etanercept and two with infliximab) were analyzed for the incidence of reported flares of anterior uveitis during treatment.⁶¹ The calculated frequency of flares of anterior uveitis in the placebo group was 15.6 per 100 patient-years, whereas patients treated with TNF blockers had significantly fewer flares (mean of 6.8 flares per 100 patient-years). Flares occurred less frequently in patients treated with infliximab (3.4 per 100 patient-years) than in those treated with etanercept (7.9 per 100 patient-years), although this difference was not significant. A more

Fig. 118.13 Radiograph of a 23-year-old man with ankylosing spondylitis and arthritis in the right hip joint. Depending on the symptoms and progression of the arthritis, this patient could become a candidate for hip replacement.

recent analysis of all published trials of AS patients treated with etanercept confirmed that the rate of uveitis flares could be reduced from 19.3 per 100 patient-years in the placebo-treated group to 8.6 in the etanercept-treated patients, a rate not significantly different from the 10.7 found in AS patients treated with sulfasalazine. A similar reduction was reported in an open-label trial of AS patients treated with adalimumab: from 15 flares per 100 patient-years before treatment to 7.4 after treatment.

Thus, although treatment with TNF blockers can reduce the frequency of anterior uveitis, the exact role of TNF blocker for severe treatment-refractory cases of anterior uveitis still has to be defined.

Osteoporosis

Osteoporosis is a frequent manifestation of AS, most probably as a consequence of limited mobility and local and general inflammation. Recently it was shown that treatment of active AS with TNF blockers induces a rather rapid improvement in bone mineral density after 6 months of treatment with infliximab or etanercept but not with placebo.

SURGICAL INTERVENTION IN ANKYLOSING SPONDYLITIS

Hip replacement

Hip arthritis (Fig. 118.13) occurs in up to a third of AS patients, most often early in the disease (first 10 years), and is more common if the disease starts

Fig. 118.14 Severe Andersson lesion (diskovertebral erosions and destruction) (a, arrow) of the thoracic spine in a patient with ankylosing spondylitis resulting in instability and severe pain, which was treated with a fusion operation (b).

Fig. 118.15 Patient with ankylosing spondylitis before (a) and after (b) correction of severe kyphosis by polysegmental wedge osteotomy. Radiographs before (c) and after (d) correction are shown. (Courtesy P. Metz-Stavenhagen, Bad Wildungen, Germany.)

early in life. Total hip replacement (THR) may be necessary in about 5% of all AS patients.² Although AS patients are normally younger than others undergoing hip replacement, the revision rate is not higher. No major difference in durability or complications is seen between cemented and non-cemented hip prostheses, but noncemented THR is regarded to be preferable in younger patients because revision is technically easier.²

Two larger studies described the results of THR in patients with AS. The first analyzed 24 young AS patients with an average age of 28.8 years at the time of surgery. Eighty-eight percent of patients became completely free of pain. After an average follow-up of 22.7 years, 88% of the original femoral components and 74% of the original acetabular components remained *in situ*. The second study reported on 340 THRs; 276 were primary and 64 were revisions. The mean age of AS patients at disease onset was 19.5 years (vs. 24.4 years for all AS patients at this center), and the mean age at the first THR was 40.0 years. Overall, 85% of patients considered the outcome to be very good. The survival rate of the original THR after 10, 15, and 20 years was 90%, 78%, and 64%, respectively, and the survival rate of revisions was 73%, 55%, and 55%, respectively.

Thus, the long-term outcome of THR in AS patients, including young ones, is good, and it should be considered an option in those with severe pain or loss of function. Although no controlled trials have investigated THR, the ASAS/EULAR experts recommended this treatment with a high level of confidence.² To avoid heterotopic bone formation and

redevelopment of ankylosis after THR, NSAID treatment should be started in AS patients (if not so treated already) before the operation and be continued for some days after.

Spinal surgery

Ankylosis of the spine results in obvious limitation of movement and elasticity. The reduced flexibility in combination with osteoporosis of the spine as a consequence of lack of movement and local and systemic inflammation renders the spine susceptible to a variety of complications, including fracture and dislocation, sometimes even after minor trauma. Spinal instability can also occur as a consequence of a severe Andersson lesion (diskovertebral erosions and destruction). Pain and neurologic involvement are indications for fusion operations (Fig. 118.14). A severe kyphotic deformity can be an indication for surgery to improve posture and forward vision, with the average correction ranging from 37 to 40 degrees. The three commonly performed procedures are opening-wedge osteotomy, polysegmental wedge osteotomy, and closing-wedge osteotomy. Severe complications such as neurologic effects occur in only 2% to 4%. Figure 118.15 shows a patient before and after correction of severe kyphosis by polysegmental wedge osteotomy of the lumbar spine, which is the location most frequently used. Atlantoaxial and atlantooccipital subluxation and spinal stenosis can be other reasons for surgical interventions.²

Classification and epidemiology of psoriatic arthritis

■ M. ELAINE HUSNI

- Psoriatic arthritis is a chronic inflammatory disease of both the skin and joints, as well as extraarticular features such as enthesitis and dactylitis.
- Five different subtypes are generally recognized; however, some overlap may occur within individual patients:
 - Distal interphalangeal joint–predominant arthritis
 - Asymmetric oligoarticular arthritis
 - Symmetric polyarticular arthritis
 - Axial disease predominant with spondylitis, sacroiliitis, and hip and shoulder involvement
 - Arthritis mutilans
- There has been a consensus to develop new classification criteria, which has led to development of the CASPAR criteria (Classification Criteria for the Study of Psoriatic Arthritis). Improved definition of the epidemiology and classification criteria for psoriatic diseases may lead to early detection and improve clinical outcomes.
- Individuals with psoriasis or psoriatic arthritis have a higher prevalence of comorbid disease, particularly cardiovascular risk factors, metabolic disorders, and other immune-mediated inflammatory issues.

INTRODUCTION

Psoriatic arthritis (PsA) is an inflammatory joint disease associated with cutaneous psoriasis. It has many diverse characteristics that can be distinguished from the more common form of inflammatory arthritis—rheumatoid arthritis (RA). In PsA, not only the joints but also the surrounding structures, such as tendons and ligaments, can be involved and be manifested clinically as dactylitis and enthesitis. In addition, PsA can affect the nails and cause pitting, ridging, and distal onycholysis. There is increasing evidence on many levels, including molecular, cellular, and tissue evidence, that PsA is a distinctive form of arthritis that includes new bone formation and inflammation. Prompt diagnosis and treatment can alleviate both pain and inflammation and possibly help prevent progressive joint involvement and damage.

The focus in this chapter is on the epidemiology and classification criteria for PsA. Some of the key features distinguishing PsA from other inflammatory disorders are also reviewed to highlight the complexity of this condition. Furthermore, it is important to recognize that the proposed categorizations of PsA may be inadequate to some degree when referring to early versus late changes, classic versus atypical manifestations, or clinical/therapeutic trials versus bedside diagnosis. It is also clear that the study of PsA has lagged behind that of other inflammatory joint diseases such as RA because to date there is no universally agreed or thoroughly validated criteria for PsA. We anticipate that as our understanding of the pathogenesis of PsA increases, the diagnostic and classification criteria will be refined to assist in earlier diagnosis of the disease.

DIAGNOSIS

A clinical diagnosis of PsA is established mainly by the presence of characteristic signs and symptoms in both the skin and joints and by the process of elimination of more common inflammatory arthritides such as RA. However, these clinical features are not confined to PsA, and both PsA and

RA share many common characteristics. The diagnosis may be easier to confirm if psoriasis coexists with symptoms of arthritis. However, in as many as 15% of cases, symptoms of PsA appear before signs of psoriasis (called “psoriatic arthritis sine psoriasis”). A careful medical history, physical examination, blood tests, and imaging of the involved joints along with dermatologic evaluation are used to diagnose PsA.

The earliest reports by Wright of inflammatory arthritis associated with psoriasis described the characteristic involvement of the distal interphalangeal (DIP) joints with erosive and terminal digital absorptive changes at the distal phalanges, concurrent sacroiliitis, and arthritis mutilans.^{1,2} The first paper from the American College of Rheumatology that identified PsA as a distinct clinical entity was published in 1964.³ More than 40 years later, we are still gathering a great deal of new information about patients with PsA, including distinct pathophysiologic mechanisms in the entheses and bone, revisions of the classification criteria, and the efficacy of novel immunologic targets.

PsA can develop at any age. However, in most people it appears between the ages of 30 and 50 years. Unlike other types of inflammatory arthritis with a large female preponderance, PsA seems to affect men equally or even at a slightly higher rate. The onset of PsA symptoms may vary in patients with psoriasis. In the majority, skin changes occur before the involvement of joints. However, this is not always a consistent feature. A subset of patients can have skin and joint symptoms concurrently. More rarely, inflammatory joint symptoms occur before skin changes. Typically, PsA is initially a mild, oligoarticular disease but can become polyarticular with time and progresses to a severe, erosive condition in at least 20% of patients. The aggressive form is seen more commonly in patients who exhibit polyarticular or erosive PsA at initial evaluation. The discovery of rheumatoid factor (RF) and, more recently, anti-citrullinated peptide antibodies has helped distinguish PsA from other inflammatory arthritides. Nevertheless, PsA is still differentiated from other inflammatory conditions predominately via clinical assessment by a physician rather than with a serologic test or widely accepted classification criteria. In general, patients with PsA are seronegative, whereas other patients with PsA can also have an increased prevalence of cardiovascular disease and its associated risk factors.

Patients with psoriasis are at increased risk for the development of PsA during their lifetime.⁴ Risk factors for the development of inflammatory arthritis in patients with psoriasis are the subject of current research, both in the area of predicting the more severe forms of PsA and in early detection/recognition, especially in nonrheumatology practices such as general internal medicine and dermatology. Given that PsA can have an indolent and progressive course, a delay in diagnosis and treatment may lead to erosive arthropathy and irreversible joint damage. The Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) has led an effort to develop and validate three PsA screening tools.⁵ To aid clinicians in screening for PsA, consensus on a well-designed screening tool can help increase detection in general and specialty clinics. It can also help in determining the prevalence of PsA in a given population, recording clinical data for genotype-phenotype studies, and tracking response to therapy. Furthermore, all patients with psoriasis should be screened for signs and symptoms of inflammatory joint disease to ensure early diagnosis and treatment of PsA. In a more recent population-based study, a psoriasis incidence cohort of 1633 patients demonstrated psoriatic features associated with a higher likelihood of PsA that included nail dystrophy, scalp lesions, and intergluteal or perianal psoriasis.⁶

Additional factors can also be predictive of a worse prognosis for psoriatic patients, including more extensive skin involvement, strong family history of psoriasis, and disease onset at an age younger than 20 years. The aggressive form is seen more commonly in those who exhibit polyarticular or erosive PsA at diagnosis.

EPIDEMIOLOGY

The ability to precisely define the epidemiology of PsA has been hampered by the lack of widely accepted classification criteria (see below). Although the exact prevalence of PsA is unknown, estimates vary from 0.3% to 1% of the U.S. population, with a reported prevalence of 7% to 42% in patients with psoriasis.^{7,8} The wide variation in estimates of prevalence stems from several factors: the large heterogeneity of the disease, lack of a precise case definition, and the diversity of cohorts being studied, which makes direct comparisons difficult. Interestingly, for the first time a recent study has shown that the incidence of PsA may be rising. A population-based incidence cohort in Olmsted County, Minnesota, demonstrated that the incidence of PsA (using the Classification Criteria for the Study of Psoriatic Arthritis [CASPAR]; see below) has been rising over a period of 30 years (1970 to 2000) in both men and women (Fig. 119.1).⁶ The results showed that the age- and sex-adjusted incidence of PsA per 100,000 increased from 3.6 (95% confidence interval [CI], 2.0 to 5.2) to 9.8 (95% CI, 27.7 to 11.9).

In a more recent review by Alamanos and associates,⁹ a total of 13 epidemiologic studies of PsA patients were systematically examined. Wide variation in the incidence and prevalence of PsA was observed in several countries and areas around the world, thus suggesting significant geographic variation in patients with PsA. For example, the prevalence of PsA in Japan is 1 case per 100,000 versus 420 cases per 100,000 in an Italian study. Pedersen and Junker¹⁰ carried out a population-based study of the

prevalence of PsA according to both the Moll and Wright criteria and CASPAR. This study found the point prevalence to be 0.15%, with an incidence of 6 per 100,000 person-years.^{9,10} A more recent population-based study of 1633 subjects with psoriasis found that PsA developed in less than 10% of the patients during the 30-year period.⁶ Two additional studies performed in Italy and Germany showed a much higher prevalence of PsA, 20.6% and 36%, respectively. Although these studies demonstrated a much greater prevalence than the 10% reported in a U.S. population-based study, all have added to our understanding of the epidemiology of PsA worldwide. A more recent study of the incidence and prevalence of PsA was performed in Buenos Aires by Soriano and colleagues.¹¹ The incidence of PsA was found to be 6.3 cases per 100,000 person-years and the prevalence was 79 cases per 100,000, which is similar to that reported in other European and U.S. studies.¹¹ Potential differences in these geographic variations could be due to secular trends, genetic factors, and study design such as differences in case ascertainment, methodology, or environmental exposure. Box 119.1 presents the methodologic challenges seen across many epidemiologic PsA studies that make it difficult to find the true prevalence and incidence of the disease.

CLASSIFICATION

Because no pathognomonic test for PsA is available to establish a definitive diagnosis, the development of well-validated and widely adopted criteria for classification has been of great interest to rheumatologists. From a historical standpoint, the main classification criteria for PsA were presented by Moll and Wright.¹² Published observations of a large cohort of patients in Leeds, England, during the early 1970s led to development of the Moll and Wright criteria (Table 119.1).^{12,13} They have been the most concise criteria and, until recently, the most widely used. The Moll and Wright criteria were based on having established inflammatory arthritis (either peripheral arthritis and/or axial involvement with sacroiliitis or spondylitis) along with the presence of psoriasis and a negative test for RF. The limitation of this classification is the fact that it was not validated with patient data or tested in diverse populations.

PsA patients have historically been classified into five different subtypes with some overlap (Box 119.2): (1) distal interphalangeal joint–predominant

Fig. 119.1 Psoriatic arthritis: epidemiology and classification.

BOX 119.1 METHODOLOGIC CHALLENGES IN EPIDEMIOLOGIC STUDIES OF PSORIATIC ARTHRITIS

- Variations in case identification or definition
- Lack of validated, widely accepted criteria for classification or diagnosis
- Different methods of case ascertainment
- Different age adjustment methods
- Small cross-sectional cohorts
- Selective study populations
- Limited follow-up period
- Lack of sensitivity of the classification criteria

TABLE 119.1

Classifications of psoriatic arthritis

Moll and Wright ¹²	CASPAR ¹³ (CLASSification criteria for Psoriatic ARthritis)*		
	Points	Category	Description
Presence of psoriasis and an inflammatory arthritis (peripheral arthritis and/or sacroiliitis or spondylitis) The (usual) absence of serologic tests for rheumatoid factor (RF)	2	Current psoriasis	Psoriatic skin or scalp disease confirmed by a dermatologist or rheumatologist;
	1	Personal or family history of psoriasis	history of psoriasis from the patient, family physician, dermatologist, rheumatologist, or other qualified practitioner; patient-reported history of psoriasis in a first- or second-degree relative
	1	Psoriatic nail dystrophy on current physical examination	Includes onycholysis, pitting, and hyperkeratosis
	1	Negative test for RF	Enzyme-linked immunosorbent assay or nephelometry preferred (no latex) using the local laboratory reference range
	1	Current dactylitis or history of dactylitis documented by a rheumatologist	Swelling of the entire digit
	1	Radiographic evidence of juxtaarticular new bone formation	Ill-defined ossification near joint margins in the hand or foot, excluding osteophyte formation on plain radiographs

*Psoriatic arthritis is diagnosed when 3 or more points are assigned in the presence of inflammatory articular disease (joint, spine, or entheses).

BOX 119.2 SUBTYPES OF PSORIATIC ARTHRITIS

- Distal interphalangeal joint—predominant arthritis (10%)
- Symmetric polyarthritis—predominant arthritis (5% to 20%)
- Asymmetric oligoarthritis or monoarthritis (70% to 80%)
- Axial disease—predominant (spondylitis and/or sacroiliitis) (5% to 20%)
- Arthritis mutilans (rare)

arthritis, (2) asymmetric oligoarticular arthritis, (3) symmetric polyarticular arthritis (RA-like picture), (4) axial disease predominant (spondylitis, sacroiliitis, and/or hip and shoulder involvement), and less commonly, (5) arthritis mutilans. Arthritis mutilans is a very rare, painful, and rapidly destructive type of PsA that is characterized by deforming arthritis, especially of the hands, and resorption of phalangeal bones. Other distinctive clinical features include dactylitis, or swelling of the fingers and toes suggestive of a “sausage-like” appearance, and inflammation of the tendon sheath (tenosynovitis) and entheses (enthesitis). *Enthesis* is the term used to describe the insertion of tendons or ligaments into bone. Inflammation of the eye such as conjunctivitis and uveitis can also be associated with PsA. Because PsA is clinically and genetically heterogeneous, it has been difficult to develop comprehensive classification criteria.

Validated criteria such as those developed for RA have not yet been fully implemented for patients with PsA. More recently, several reports have highlighted specific modifications of the Moll and Wight subgroups.¹⁴⁻¹⁶ A more recent and unified effort of expert investigators has led to development of CASPAR.¹³ Considered one of the largest international endeavors, it established a consensus based on 32 centers worldwide. The study evaluated 588 patients with definite PsA versus 536 controls (patients with other forms of inflammatory arthritis) to collect standardized data. This very thorough effort culminated in CASPAR, which yielded a sensitivity of 98.7% and specificity of 91.4% for the diagnosis of PsA. The new classification criteria incorporated musculoskeletal, dermatologic, and radiographic features. The main limitation of the CASPAR study cohort is the long-standing (>12 years' duration), well-established diagnosis of PsA in the participants, thus possibly losing generalizability to those with early disease. Chandran and colleagues¹³ undertook a study to determine the sensitivity of CASPAR

in patients with early PsA (duration of disease < 1 year) and found these criteria to have very high sensitivity for both early and late PsA disease. We need to realize, however, that this study was undertaken in a specialty clinic of a tertiary referral center without a control group, thus possibly leading to overestimation of the sensitivity of the criteria. An additional limitation of CASPAR is the complexity of the principal qualification for inflammatory arthritis (peripheral, spinal, or enthesal disease), which may be difficult for a nonrheumatology health care provider to confirm. Performance of CASPAR has not been studied in cohorts with early disease. Van den Berg and colleagues¹⁷ demonstrated that CASPAR was 88.7% sensitive and that the Assessment of SpondyloArthritis international Study (ASAS) and European Spondylarthropathies Study Group (ESSG) criteria reached 48.7% in an early-spondyloarthritis cohort.

It is important to remember that fulfilling classification criteria is not equivalent to making a diagnosis in an individual patient.¹⁸ It is appropriate to have separate criteria for classification and diagnostic purposes. The use of validated classification criteria for various inflammatory chronic diseases such as RA has been demonstrated to be critical for rigorous research. The development of new therapies, particularly biologic disease-modifying antirheumatic drugs, has highlighted this shortfall and created a need for more sensitive and specific criteria and for standardized outcome and response. The situation is made more complex in PsA by the existence of several clinical subgroups, for which precise definition has been the subject of some debate, as well as by the considerable overlap of the subgroups. The problem is not so critical with the classic manifestation of PsA—oligoarthritis, DIP joint involvement, calcaneal enthesitis, and dactylitis—but becomes more problematic with the group of patients who have seronegative polyarthritis and psoriasis.

During the past decade the overall prognosis of patients with PsA has steadily improved. However, for optimal treatment and best practice outcomes, further attention must be given to classification criteria for the entire spectrum of psoriatic disease. Psoriatic diseases should not be thought of as a condition limited to the skin and joints but also as a systemic inflammatory condition.¹⁹ Evidence is increasing that individuals with psoriasis or psoriatic arthritis have a higher prevalence of comorbid disease, particularly cardiovascular risk factors, metabolic disorders, and other immune-mediated inflammatory issues.²⁰ As we better define the epidemiology and classification criteria for psoriatic diseases, the ability to detect patients with psoriatic diseases earlier may assist in improving clinical outcomes in these patients.

Clinical features of psoriatic arthritis

■ IAN N. BRUCE ■ PAULINE Y.P. HO

- Psoriatic arthritis is an inflammatory arthritis associated with psoriasis; tests for rheumatoid factor are usually negative.
- In 15% of patients psoriasis develops after the onset of arthritis.
- Nail changes have the strongest association with arthropathy; the distal interphalangeal joints are particularly affected.
- Typical clinical features include the following:
 - Distal interphalangeal joint involvement
 - Asymmetric sacroiliitis/spondylitis
 - Dactylitis
 - Enthesitis
- The number of joints involved can increase with disease duration.
- Patients with polyarticular involvement tend to have poorer long-term outcomes.

HISTORY

Psoriatic arthritis can be defined as “an inflammatory arthritis associated with psoriasis, which is usually negative for rheumatoid factor.”¹ Alibert first described the association between psoriasis and arthritis in 1818, although the term *psoriasis arthritique* was first used by Bazin in 1860. Bourdillon developed a more detailed description of the condition in 1888.¹ In the 1950s, Wright² formally described psoriatic arthritis and pointed out the low frequency of rheumatoid factor (RF) positivity, its predilection for distal interphalangeal (DIP) and sacroiliac joint involvement, the asymmetric nature of the arthritis, and its tendency to result in severe joint destruction (arthritis mutilans). In 1964 the American Rheumatism Association recognized psoriatic arthritis as a distinct entity.

CLINICAL FEATURES

Classification criteria

Psoriatic arthropathy is classified within the group of seronegative spondyloarthritis (see Chapter 113) on the basis of work by Moll and Wright¹ and others. Psoriatic arthritis is also included within the European Spondylarthropathies Study Group (ESSG) criteria. To facilitate further research on psoriatic arthritis, a new criteria set has been developed and validated. The CASPAR (CLASsification criteria for Psoriatic ARthritis) criteria³ have been shown to have high sensitivity and specificity for the diagnosis of psoriatic arthritis and provide a more consistent framework on which to base case ascertainment for future clinical and basic research on this condition (Box 120.1).

Articular involvement

Joint involvement in psoriatic arthritis can vary considerably, from isolated monoarthritis to extensive destructive arthritis, and can involve peripheral joints and the axial spine. The most widely used descriptive classification is that proposed by Moll and Wright,¹ which identifies five major subtypes of psoriatic arthritis (Box 120.2). Many further attempts have been made to revise and modify this system, but they have not been widely adopted. Categories within these subtypes have a high degree of overlap; for example,

spondyloarthritis may be the dominant feature in only a minority of patients, whereas clinical and radiologic involvement of the spine can be detected in approximately a third of cases.⁴ Similarly, exclusive involvement of the DIP joint is less common than involvement of this joint as part of a general peripheral arthritis.^{5,6} Many series have therefore shown quite marked differences in the relative frequencies of these subtypes. This is partly related to the criteria for entry into these cohorts and differences in the definitions used for each subgroup and the duration of disease at the time of the study (Table 120.1 and Fig. 120.1).⁵ For example, Jones and associates⁵ found that although the majority of patients described monoarticular or oligoarticular disease at onset, after a mean follow-up of 12.1 years, 63% of patients had polyarthritis. Marsal and coworkers⁷ also found that the median number of joints affected at the onset of disease was 2 (range, 0 to 8), as compared with a median of 10 (range, 2 to 19) after a follow-up period of 8 years. Arthritis mutilans is also a feature of prolonged disease,⁵ and the frequency of spinal involvement tends to increase with time. A more pragmatic classification based simply on peripheral or axial involvement has therefore been suggested and may be justified.⁷ This more pragmatic classification also seems to be generally true of other forms of spondyloarthritis inasmuch as the Assessment of SpondyloArthritis international Society (ASAS) published classification criteria for both axial and peripheral spondyloarthritis.

Symmetry of involvement in psoriatic arthritis

Wright² identified asymmetry as a common feature of psoriatic arthritis, particularly with the oligoarticular pattern,¹ a finding supported by other investigators.^{4,5} In contrast, the majority of patients with polyarticular disease have symmetric involvement.^{3,8} Symmetry may in part reflect the total number of joints involved. In a comparison of patients with early and late rheumatoid arthritis (RA) and psoriatic arthritis, after correction for the total number of involved joints, no difference was found in the degree of joint symmetry observed between these conditions.

Distal interphalangeal joint involvement

Involvement of the DIP joints in psoriatic arthritis is considered a distinctive feature of this condition (Fig. 120.2). These joints are involved more frequently in psoriatic arthritis than in inflammatory arthritis without psoriasis.⁹ In a community-based survey of early inflammatory arthritis, a DIP-predominant pattern at onset was found in 3.9% of patients with psoriasis versus 0.3% of those without psoriasis.¹⁰ Several large clinic series have noted involvement of the DIP joints in up to 54% of patients as part of polyarthritis,^{4,6} whereas the DIP-predominant subgroup represented a much smaller proportion of cases (1% to 16%) and its presence was often confined to early disease.^{1,6} DIP joint involvement is also associated with dactylitis^{4,6} and nail dystrophy.² Recent studies using magnetic resonance imaging (MRI) have noted a close association between involvement of the DIP joint and the nail–distal phalanx complex, which may explain this clinical association.¹¹

Monoarticular and oligoarticular arthritis

The frequency of these subtypes is highly variable across series and ranges in prevalence from 11% to 70%.^{1,4} In a community-based study of psoriatic arthritis in the United States, 90% of patients with psoriatic arthritis had an oligoarticular pattern at onset.¹² As pointed out earlier, monoarthritis and oligoarthritides are the most common patterns seen initially.^{5,7,12} A high proportion will, however, progress to additional joint involvement.⁵ In addition to involvement of the lower limb joints, this pattern of arthritis can fre-

quently affect the small joints of the hands, including the proximal interphalangeal and DIP joints. This pattern also has a male preponderance.⁶

Symmetric polyarthritis

Symmetric polyarthritis involves the small joints of the hands and feet, in addition to larger joints (Fig. 120.3). It has a female preponderance^{4,6,13} and can be clinically indistinguishable from RA.^{2,8} The exact frequency of this pattern is again controversial. Shbeeb and coworkers¹² described a 3% prevalence of polyarthritis at onset, whereas in hospital series polyarthritis may affect 15% to 61% of individuals.^{1,4,12} Patients with polyarticular disease tend to have a longer duration of disease than do those with other more discrete patterns.^{5,6} Regardless of the precise frequency of polyarthritis, it is patients with this condition who have more evidence of erosive joint damage.^{6,7}

Arthritis mutilans

Arthritis mutilans is a commonly used term with no clear definition. In general, it describes the end stage of a destructive erosive arthritis, with disorganization of joints leading to subluxation, “flail” joints, and digital telescoping—the so-called *doigt en lorgnette* (opera glass finger) (Figs. 120.4 and 120.5).² In most series its prevalence is lower than 5%.^{1,5,6} *Arthritis mutilans* is associated with long-standing disease and a female preponderance.^{5,7} An association with sacroiliac joint involvement has also been described.^{1,7}

BOX 120.1 CLASSIFICATION CRITERIA FOR PSORIATIC ARTHRITIS (CASPAR)

- Inflammatory articular disease (joint, spine, or enthesitis)
- AND at least 3 points from the following:
 - Current psoriasis (2 points), a personal history of psoriasis (1 point), or a family history of psoriasis (1 point)
 - Typical nail dystrophy (1 point): onycholysis, pitting, hyperkeratosis
 - Negative rheumatoid factor test (1 point): enzyme-linked immunosorbent assay or nephelometry preferred
 - Dactylitis (1 point): current dactylitis or a previous episode noted by a rheumatologist
 - Juxtaarticular new bone formation (1 point) on hand or foot radiographs

From Taylor W, Gladman D, Helliwell P, et al. Classification criteria for psoriatic arthritis: development of new criteria from a large international study. *Arthritis Rheum* 2006;54:2665-73.

BOX 120.2 MOLL AND WRIGHT CLASSIFICATION OF PSORIATIC ARTHRITIS

- Arthritis with predominant distal interphalangeal joint involvement
- Arthritis mutilans
- Symmetric polyarthritis—indistinguishable from rheumatoid arthritis
- Asymmetric oligoarticular arthritis
- Predominant spondylitis

From Moll JMH, Wright V. Psoriatic arthritis. *Semin Arthritis Rheum* 1973;3:55-78.

Spondyloarthritis

The spondyloarthritis of psoriatic arthritis is uncommon as a predominant feature and accounts for only approximately 5% of cases.^{1,4} Careful clinical and radiologic assessment, however, reveals involvement of the axial spine in 20% to 40% of cases,^{4,6,13} a figure that increases to as high as 51% at long-term follow-up. Involvement of the sacroiliac joints can be symmetric or asymmetric. Patients with bilateral sacroiliitis have a stronger association

Fig. 120.1 Time-dependent trends in the relative frequencies of specific subgroups of psoriatic arthritis.

with HLA-B27.¹³ In contrast to ankylosing spondylitis, this form of spinal disease carries a better prognosis,¹⁴ which may partly reflect the random nature of spinal involvement, as well as a lower frequency of zygapophyseal joint fusion than seen in psoriatic arthritis. Cervical spine involvement in psoriatic arthritis can occur as part of more widespread axial disease or as the sole site of axial involvement and becomes more frequent with time. Two main types of cervical spine changes are described: an ankylosing type, similar to that seen in ankylosing spondylitis, and an erosive or inflammatory type, which can result in atlantoaxial or subaxial instability. Because cervical spine involvement can be clinically silent, patients with psoriatic arthritis, particularly those with long-standing disease, should have cervical spine radiographs taken and evaluated before receiving general anesthesia.

Other musculoskeletal features

Dactylitis

Dactylitis, or “sausage digit,” represents complete swelling of a single digit in the hand or foot. Dactylitis occurs in 30% to 40% of patients during the course of their disease.^{4,6} It most commonly involves one or two digits at a time, and the feet are affected more commonly than the hands (Fig. 120.6).¹⁵ There is an association with involvement of the DIP joint,^{4,6} and erosive damage more frequently develops in patients with dactylitis.^{7,15} MRI has revealed dactylitis to be strongly associated with flexor tenosynovitis, soft tissue edema, bone edema, and synovitis.^{16,17}

Enthesitis

Inflammatory lesions at the insertion of tendon into bone are a hallmark clinical feature of spondyloarthritis, and indeed, it has been postulated that this inflammatory lesion is the key central pathogenic process in all forms of seronegative spondyloarthritis.¹⁸ Symptomatic enthesitis occurs in 20%

Fig. 120.5 (a and b) Digital telescoping in arthritis mutilans. (© University of Manchester.)

Fig. 120.6 Dactylitis of the second toe.

to 40% of patients with psoriatic arthritis.^{18,19} It has been reported to be an initial feature in 4%.¹⁹ Common sites of enthesitis include the Achilles tendon (Fig. 120.7), the plantar fascia insertion into the calcaneus, and ligamentous insertions into the pelvic bones. With the advent of ultrasound, patients with psoriasis and more extensive nail involvement have also been noted to have higher systemic enthesopathy scores.²⁰

Peripheral edema

In contrast to the remitting seronegative symmetric synovitis with peripheral edema (RS3PE) syndrome, the distal extremity swelling in psoriatic arthritis is frequently asymmetric and preferentially affects the lower limbs. It can occur at any time and may be an initial feature of the disease. Peripheral edema is associated with extensor tenosynovitis and local enthesitis, and the edema is often found along the course of the involved tendon. Peripheral edema is usually responsive to oral corticosteroids. Several cases of lymphedema associated with psoriatic arthritis have also been reported. Though generally less painful, lymphedema can become more extensive and has been associated with progression of erosive damage. The response to corticosteroids and disease-modifying antirheumatic drugs varies, and it can be an additional source of disability in these patients.

Synovitis, acne, pustulosis, hyperostosis, and osteitis syndrome

The syndrome of synovitis, acne, pustulosis, hyperostosis, and osteitis (SAPHO) is an uncommon but recognized subgroup of psoriatic arthritis. Clinically, less than 3% of patients with psoriatic arthritis are found to have SAPHO syndrome at initial evaluation. Nevertheless, at least 67% of all patients with SAPHO syndrome have psoriasis vulgaris or palmoplantar pustulosis.²¹ Scintigraphy suggests that involvement of the anterior chest wall may occur at a much greater frequency in patients with psoriatic arthritis than is clinically recognized.⁸

Fig. 120.7 Enthesitis involving the insertion of the right Achilles tendon.

Psoriatic onychopachydermoperiostitis

The key features of this rare manifestation include severe involvement of one or more terminal phalanges with associated severe nail dystrophy, soft tissue swelling, and marked periosteal reaction of the distal phalanx noted radiologically. Involvement of the DIP joint appears to be variable but is difficult to assess because of the marked local inflammation.²² Involvement of the great toe in particular had been described in this condition, and marked periostitis may eventually result in the radiologic phenomenon of the “ivory phalanx.” This entity appears to reflect the previously mentioned close association between the DIP joint, distal phalanx, and nail insertion as an extended enthesal complex.¹¹

Associated nail and skin changes

Skin changes

There is a suggestion that patients with psoriatic arthritis may have more extensive psoriasis than those with uncomplicated psoriasis only and that severe skin disease may increase the risk for development of psoriatic arthritis.²³ However, in general, most patients with psoriatic arthritis have only mild to moderate skin disease.²⁴ There is also no correlation between the extent of skin disease and total joint scores in patients with psoriatic arthritis.^{3,24} Nevertheless, 30% to 40% of patients with psoriatic arthritis report synchronicity of flares of their joint and skin disease, although the validity of this observation has not been formally tested.^{2,4} In a recent community-based psoriasis cohort, the pattern of psoriasis was found to be associated with future risk for psoriatic arthritis. In particular, scalp or intergluteal/perianal involvement is associated with increased risk for the development of arthritis.²⁵ With regard to specific psoriatic arthritis subtypes, an association between palmoplantar pustulosis and the SAPHO syndrome has been described.

Nail involvement

In contrast to skin disease, there is a close association between nail and joint involvement in psoriatic arthritis. Nail involvement is a risk factor for the future development of psoriatic arthritis²⁵; although onset of the skin disease may precede onset of the arthropathy by an average of 7 to 10 years, onset of the nail changes often occurs only 1 to 2 years before the onset of arthropathy.² Nail involvement occurs in 20% to 40% of patients with uncomplicated psoriasis, whereas 60% to 80% of patients with psoriatic arthritis have nail involvement.⁴⁻⁶ Anatomically, the nail is closely related to the distal phalanx by Sharpey fibers that insert into the bone in a manner similar to an enthesis. In addition, the extensor tendon entheses insert into the area adjacent to the nail root.¹¹ All the typical nail changes of psoriasis can be observed in psoriatic arthritis, including pitting, ridging, hyperkeratosis, and onycholysis.¹ The association between nails and joints is particularly marked in the presence of DIP joint arthritis, and 80% to 100% of such patients have nail involvement that frequently occurs at the adjacent nail (Fig. 120.8).^{2,5,6} Patients with DIP joint involvement also have more severe nail changes,^{5,9} and patients with nail disease have more DIP joint involvement.²⁴ There is also closer synchronicity between flares of DIP joint disease

Fig. 120.8 Involvement of the joint and adjacent nail in the right hand (a) and in the foot (b). Note the lack of involvement of the right fourth finger and nail. (© University of Manchester.)

and worsening of nail involvement than is reported for flares of skin and joint disease.²

Other extraarticular features

The extraarticular features observed in psoriatic arthritis overlap with those of the other forms of seronegative spondyloarthritis. Ocular inflammation can occur and is most frequently manifested as conjunctivitis. However, iritis has also been described in 7% of those affected by psoriatic arthritis.⁴ Additional uncommon complications such as oral ulceration, urethritis, and aortic valve disease have likewise been reported.²⁶

JUVENILE PSORIATIC ARTHRITIS

Psoriatic arthritis in those younger than 16 years is relatively uncommon and appears to account for less than 10% of chronic arthritis cases in childhood.²⁷ In contrast to adult-onset psoriatic arthritis, in juvenile-onset psoriatic arthritis the arthropathy precedes psoriasis in up to 50% of cases.²⁸ Careful attention therefore needs to be paid to examination of the nails and taking an accurate family history in children with arthritis (Table 120.2).²⁸ Juvenile psoriatic arthritis has a female preponderance of 2:1 to 3:1.²⁸ It is frequently manifested as monoarthritis or oligoarthritis, and the knee is often the first joint affected. Progression to polyarthritis occurs in a significant proportion of those affected, and involvement of the small joints of the hands and feet occurs commonly during the course of disease.²⁸ The other typical musculoskeletal features of adult psoriatic arthritis, such as dactylitis, enthesitis, and DIP joint involvement, are all recognized. In addition, chronic uveitis is reported in 10% to 15% of patients and may be associated with antinuclear antibodies.²⁸ There is also evidence of two subgroups of juvenile psoriatic arthritis. The first subgroup has an onset around 2 years of age and predominantly consists of females. This population has a very low prevalence of actual psoriasis and tends to have a more oligoarticular disease with less axial involvement but a very high prevalence of dactylitis; in one study, 60% of this cohort was antinuclear antibody positive. In the second subgroup, psoriatic arthritis is diagnosed at a median age of 9.5 (range, 6.2 to 11) years, and such children are more likely to have axial disease, enthesitis, and polyarticular arthritis. Interestingly, uveitis had a similar prevalence in both populations. The prognosis of children with juvenile psoriatic arthritis is good. It can, however, persist into adulthood, and 10% to 15% of those affected have significant residual disabilities.²⁹

INVESTIGATIONS

Laboratory investigation

No laboratory tests are diagnostic of psoriatic arthritis. Several studies have shown that the acute-phase reactants display typical inflammatory changes when the disease is active. In particular, anemia of chronic disease, hypoalbuminemia, and an increased erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) and fibrinogen levels are described.³⁰ Hypergammaglobulinemia with increased IgG and IgA is observed.⁴ Increased IgA is

especially associated with spondyloarthritis.¹³ Monoclonal gammopathy has also been reported in 9.7% of patients with psoriatic arthritis in one series and is associated with older age, longer disease duration, more active disease, and less intensive therapy.³¹ Overall, the ESR and CRP show good correlation with inflammatory disease activity, particularly in polyarticular disease.^{8,13} Because in most series positive RF is not taken as an absolute exclusion criterion for the case definition of psoriatic arthritis, RF-positive status has been reported in 5% to 10% of patients.^{4,13} In a community cohort of patients with recent-onset inflammatory polyarthritis, those with psoriasis were significantly less likely to be RF positive than were those without psoriasis (13% vs. 31%).¹⁰ Anti-citrullinated peptide antibodies (ACPAs) have also been reported to have a low prevalence of 6% to 10% in psoriatic arthritis.³²⁻³⁵ Like RF positivity, there is an association with female gender and polyarticular disease.³³⁻³⁵ It has also been noted, however, that other typical psoriatic features such as DIP involvement and enthesitis are likewise observed in ACPA-positive patients.^{32,33} Positivity for antinuclear antibody is also found in 10% to 14% of patients with psoriatic arthritis.^{4,13} Hyperuricemia is present in up to 20% of patients with psoriatic arthritis.³⁶ A prospective study of patients with psoriatic arthritis found that the best predictors of hyperuricemia were renal impairment and increased total cholesterol. No correlation with the extent or severity of skin involvement was found, so hyperuricemia does not primarily reflect increased epidermal cell turnover.³⁶ Hyperuricemia should therefore alert the physician to assess the patient for other components of metabolic syndrome, such as abdominal adiposity, higher blood pressure, and dyslipidemia.

Radiographic changes

Peripheral joint features

Many radiologic features reflect the clinical distribution of psoriatic arthritis described earlier. Therefore, involvement of the DIP joints (Fig. 120.9) and an asymmetric distribution when few joints are affected are well described. In addition, involvement of enthesal sites can result in proliferative new bone formation at sites of predilection, such as the plantar fascia and Achilles tendon insertions. With regard to the onset of erosive changes in peripheral joints, in a community survey of early inflammatory arthritis, the risk for development of erosions at 1 year was lower in patients with psoriasis than in those without psoriasis.¹⁰ This reduced risk was explained by the lower incidence of RF positivity in the psoriasis group. Nevertheless, 22% of patients with psoriasis and early arthritis had evidence of erosions at 1 year.¹⁰ In more established hospital cohorts, the prevalence of erosions can range from 35% to 70%.^{4,6,7} Erosions are most frequent in patients with polyarthritis and in those with a longer disease duration, as well as in those

Fig. 120.10 Arthritis mutilans. (a and b) Marked osteolysis and “penciling” have resulted in complete disorganization of the metatarsophalangeal (MTP) joints. There is also a “pencil-in-cup” deformity of the right fifth MTP joint (b). (© Dr. R. Whitehouse.)

with dactylitis.^{6,7} Patients with psoriatic arthropathy also tend to have a lower prevalence of erosions at the wrist and more erosions at the DIP joints than RA patients do.³⁷ In addition to erosions, soft tissue swelling can be seen around sites of active inflammation, although periarticular osteopenia is not a feature of psoriatic arthritis.³⁸ The other peripheral joint radiographic features can be broadly grouped into destructive and proliferative changes.

Destructive changes

Osteolysis may result in whittling or penciling of a phalanx. This can occur alone or in association with erosion at the base of the adjacent phalanx, which causes the classic “pencil-in-cup” deformity.³⁹ Such destruction is typical of the arthritis mutilans pattern of disease (Fig. 120.10).

Proliferative changes

In periostitis, proliferative new bone formation can occur along the shaft of the metacarpal and metatarsal bones (Figs. 120.11 and 120.12a). When this change occurs adjacent to an erosion, the term *whiskering* is often used (see Fig. 120.12b).³⁹

An ivory phalanx (see “*Psoriatic onychopachydermoperiostitis*,” earlier) can be noted, as can bony ankylosis and joint fusion (Fig. 120.13).

Spinal changes

Asymmetric sacroiliitis is more common in psoriatic arthritis than in ankylosing spondylitis (Fig. 120.14). Many of the classic features of ankylosing spondylitis can be observed in psoriatic arthritis, but patients with psoriatic arthritis tend to have less frequent involvement of the zygapophyseal joint and less severe and extensive involvement of the lumbar spine. Overall, the spinal involvement in psoriatic arthritis tends to be more “spotty” and asymmetric, with frequent involvement of the cervical spine. An additional feature in the spine is paravertebral ossification or “chunky” syndesmophytes.⁴⁰ These bony outgrowths appear to be distinct from the classic “marginal” syndesmophytes observed in ankylosing spondylitis. The chunky syndesmophytes again occur in a patchy and asymmetric fashion throughout the axial spine (Fig. 120.15).

Fig. 120.11 Asymmetric involvement of the hands. Soft tissue swelling and a periosteal reaction are evident in the right second and third fingers in the typical “ray” distribution. (© Dr. R. Whitehouse.)

Other imaging modalities

MRI studies have demonstrated that in psoriatic arthritis, extraarticular tissues such as ligaments, periarticular soft tissue and tendon sheaths, and bone are frequently involved (Fig. 120.16).^{16,41} In addition to delineating clinical joint involvement, MRI has demonstrated evidence of “subclinical” musculoskeletal changes in a significant proportion of patients with apparently uncomplicated psoriasis. Scintigraphy in patients with psoriatic

arthritis has also demonstrated more extensive involvement than is appreciated clinically, particularly in the anterior chest wall and large peripheral joints.⁸ Such techniques can therefore facilitate clinical evaluation of patients with psoriasis and articular complaints.

DIFFERENTIAL DIAGNOSIS AND CLINICAL EVALUATION

Differential diagnosis

Psoriatic arthritis poses an important diagnostic challenge, and the wide range of clinical manifestations described earlier means that the differential diagnosis is extensive. Given the frequency of hyperuricemia, crystal arthropathies also need to be excluded, and accordingly, joint fluid analysis may need to be performed. The distinctions between psoriatic arthritis and RA or psoriatic arthritis and ankylosing spondylitis have been discussed and are summarized in [Tables 120.3](#) and [120.4](#). In patients without any clinical

TABLE 120.3
Key features that help distinguish between psoriatic arthritis (PsA) and rheumatoid arthritis (RA)

Feature	PsA	RA
Gender (M:F)	1:1	2:1
Rh factor	<10%	80%
DIP joints	30%-50%	Uncommon
Pattern of joint involvement	Asymmetric “ray” pattern	Symmetric “row” pattern
Sacroiliac joints/axial spine	35%—any level	Cervical spine in late disease
Other musculoskeletal disorders	Enthesitis Dactylitis Periarticular erythema	
Extraarticular	Skin Nail dystrophy	Nodules Sicca Vasculitis
Radiology	Erosion (distal interphalangeal joints) Periostitis/bony proliferation	Periarticular osteopenia Erosion (wrists)

Fig. 120.15 Nonmarginal “chunky” syndesmophytes.

Fig. 120.16 Involvement of extraarticular tissues in psoriatic arthritis. Magnetic resonance images (coronal fat suppressed, proton density weighted) show osteitis and bone edema as high signal in the clavicles, manubrium, and upper part of the sternum in a patient with the syndrome of synovitis, acne, pustulosis, hyperostosis, and osteitis (SAPHO). evidence of skin or nail disease—“psoriatic arthritis sine psoriasis”—distinguishing psoriatic arthritis from other arthropathies, including erosive or inflammatory osteoarthritis, is particularly difficult.

Clinical evaluation

Patients with psoriatic arthritis can be less tender over affected joints than patients with RA, and effusions can be more difficult to detect. It is therefore easy to underestimate the extent of joint involvement in psoriatic arthritis. Examination for other musculoskeletal features such as enthesitis, tenosynovitis, and axial spine involvement is also necessary. Limitations in spinal movement may not follow the classic pattern observed in ankylosing spondylitis and may be confined to the neck or thoracic spine in the absence of lumbar spine or sacroiliac joint involvement. Radiologic evaluation complements the clinical examination in that joint damage from previous involvement may be detectable radiologically in the absence of current symptoms. Similarly, previous or current inflammatory back symptoms suggest spondylitis and require radiologic examination. Finally, detailed examination of the skin and nails to include “hidden areas” such as the scalp, perineum, and periumbilical area is important (Fig. 120.17). The choice of therapeutic agent or agents is determined by the extent and severity of the skin and joint disease and by estimation of the risk for progression of disease.

PROGNOSIS

Functional impairment

Only a few prospective studies of prognosis in patients with psoriatic arthritis have been conducted. The general impression is that the condition is associated with less long-term disability than is observed with RA.¹ Several hospital clinic series have, however, shown that between 11% and 42% of patients with psoriatic arthritis have American College of Rheumatology grade III or IV functional impairment at the time of study.^{4,6,7,13} Direct comparison between patients with psoriatic arthritis, RA, and ankylosing spondylitis also shows a comparable burden of illness across these conditions.⁴² All studies are in agreement that there is an association between polyarthritis and functional disability. One study found that patients with at least five joint effusions at initial evaluation in the clinic were significantly more likely to exhibit progressive joint deformity at follow-up. Additional predictive factors include the presence of HLA-B27, HLA-B39, or HLA-DQw3.⁴³

Mortality

A community-based study in Olmsted County, Minnesota, showed no difference in survival of patients with psoriatic arthritis and members of the general population.¹² In contrast, in a hospital cohort, an increased mortality rate in comparison to the general population was observed, with an overall standardized mortality ratio of 1.36 (95% confidence interval, 1.12 to 1.64)⁴⁴; this probably reflects the spectrum of disease with long-term follow-up in hospital clinics. Interestingly, there was also evidence that the standardized mortality rate has improved with calendar year such that in the 1996-2004 cohort, no excess mortality was noted.⁴⁴ The most common

causes of mortality in patients with psoriatic arthritis included cardiovascular disease, neoplasia, and respiratory disease.^{44,45} Others have also shown an excess burden of cardiovascular disease in those with psoriatic arthritis.⁴⁶⁻⁴⁸ Significant predictors of mortality in patients with psoriatic arthritis include radiologic damage, increased ESR, and previous use of disease-modifying

antirheumatic drugs, with nail lesions being identified as a “protective factor.”⁴⁹ From these studies one can conclude that patients with polyarthritides are most likely to have functional impairment and progression of disease. In addition, extensive and progressive disease may also be associated with excess mortality.

Etiology and pathogenesis of psoriatic arthritis

■ CHRISTOPHER RITCHLIN ■ DENNIS MCGONAGLE

- Psoriatic arthritis (PsA) is an inflammatory arthropathy associated with psoriasis, but not all patients with the characteristic arthropathy have skin disease.
- The heterogeneity in expression of PsA with diverse skeletal patterns of involvement is a hallmark of the disease not observed in rheumatoid arthritis (RA). Whereas RA is considered an autoimmune-mediated peripheral synovitis that leads to bone destruction, the phenotype of PsA is strikingly different, with characteristic features of florid bone destruction (including erosion and osteolysis) and new bone formation that encompasses periostitis, joint ankylosis, and syndesmophyte formation.
- This heterogeneous pattern of pathobiology in PsA is best conceptualized in relation to inflammation at “the entheses organ,” which includes the soft tissue structures adjacent to the insertion, regional trabecular bone, and the associated synovium, all of which form a musculoskeletal assembly called the synovial/enthesal complex. As yet poorly defined, immune dysfunction at the entheses organ probably contributes to much of the local skeletal inflammation in PsA.
- Nail disease, including matrix and nail bed involvement, is characteristic of PsA but less common in psoriasis. Recent evidence indicates that neither nail disease nor joint disease shares the strong HLA-Cw06 genetic association noted in early-onset psoriasis. Moreover, inflammation at the entheses may be a link between distal joint arthritis and nail involvement in PsA.
- Imaging studies have convincingly demonstrated that psoriasis without clinical arthritis is strongly associated with subclinical abnormal signals in entheses and bone. These studies, coupled with the association of PsA with a wide array of extraarticular features, including uveitis, inflammatory bowel disease, obesity, metabolic syndrome, cardiovascular disease, and frequent nail inflammation, support the emerging concept of a wide spectrum of disease that can be viewed as psoriatic disease.
- The entire spectrum of skeletal and cutaneous inflammation associated with PsA is remarkably responsive to blockade of tumor necrosis factor (TNF) in the majority of patients, which underscores the pivotal role of this cytokine in disease pathogenesis. Recent studies have indicated that blockade of p40, the common subunit of interleukin-12 (IL-12) and IL-23, is effective for both skin and joint inflammation as well.
- Genome-wide association studies have confirmed several genetic associations with psoriasis. The B8, B27, B38, and MICA alleles of HLA are significantly associated with PsA as opposed to psoriasis. Other associated risk alleles include molecules involved in signaling through the IL-23, IL-17, and TNF receptors.

INTRODUCTION

The first definitive description of the link between psoriasis and arthritis was elucidated in a seminal paper published by Wright in 1956.¹ In a landmark paper published in 1973, Moll and Wright² described the characteristic features of psoriatic arthritis (PsA) in more detail and emphasized the diversity of its clinical manifestations, such as asymmetry, arthritis mutilans, enthesitis, dactylitis, and nail disease, findings not generally observed in rheumatoid arthritis (RA).³

Over the past 35 years, scientific and translational studies have supported the concept that PsA has distinct disease mechanisms that contrast sharply

with the key pathophysiologic events associated with RA, although some parallels exist. In this chapter, genetic and environmental factors are discussed, and a comprehensive review of the alterations that take place in the skin, synovium, entheses, cartilage, and bone is presented. In addition, relevant observations obtained from the study of animal models are highlighted, and both human and preclinical data are incorporated into a working model of disease pathogenesis.

GENETIC FACTORS

Epidemiologic reports, association studies, and genome-wide association scans (GWAS) indicate that PsA is a highly heritable disease mediated by multiple genes with low-risk effects.⁴ Heritability as measured by λ s (risk to siblings vs. risk in the general population) was greater than 27, as compared with 4 to 7 for psoriasis.⁵⁻⁷ Of note, one twin study did not find the concordance rate to be higher in dizygotic twins than in monozygotic twins, but the study was underpowered.⁸ The recent development of classification criteria⁹ may help improve diagnostic precision, and larger sample sizes that include subjects with well-characterized psoriasis and PsA should facilitate better understanding of the genetic factors associated with the two disorders.

Genome-wide association scans have shown that IL-23R and HLA-Cw06, along with molecules involved in NF- κ B gene expression (TNIP1) and signaling (TNFAIP3), and tumor necrosis factor (TNF) polymorphisms are observed with greater frequency in PsA subjects than in controls (Table 121.1). Association studies and GWAS have also identified risk alleles in patients with both psoriasis and PsA, including interleukin-12A (IL-12A), IL-12B, IL-23 receptor (IL-23R), genes that regulate nuclear factor κ B (NF- κ B), TNIP1, and the class I major histocompatibility complex (MHC), particularly HLA-Cw6 and HLA-B27 (see Table 121.1).¹⁰⁻¹⁷ Closer examination of the association with HLA-Cw06, however, revealed that the presence of the allele primarily relates to the early onset of psoriasis and not arthritis¹⁸ and, likewise, that the IL-23R association appears to be more strongly linked to psoriasis than to arthritis.¹¹

TRAF3IP3 or Act1 is an adaptor protein in the IL-17R complex that is essential for type 17 helper T cell (Th17)-mediated inflammatory responses. It is now apparent that a variety of other cells, including monocytes and epithelial cells, can also release IL-17.¹⁹ The mutation in Act1 is associated with increased production of IL-22, a cytokine linked to keratinocyte proliferation in the skin and bone formation, as discussed later.²⁰ Of note are recent findings showing an increased frequency of HLA-B27 in PsA, and the presence of this allele is associated with a short interval between the onset of skin and joint disease.¹⁶ Other studies have found an association with MHC class I chain-related gene A (MICA) alleles that are situated centromeric to the HLA-B locus, and this susceptibility was independent of HLA-Cw6.^{21,22} Overall, the MHC associations have the strongest relative risk, but defining specific alleles is complicated by the strong linkage disequilibrium characteristic of this region.⁴ The association with killer immunoglobulin-like receptor (KIR) alleles is particularly fascinating because these receptors bind MHC class I molecules with locus and allele specificity and this interaction can result in both activating and suppressive signals to natural killer cells and lymphocytes that are dependent on the ligand-receptor interaction.²³

A recent high-density GWAS study in individuals with inflammatory bowel disease showed a remarkably strong genetic overlap with both psoriasis and ankylosing spondylitis, thus adding further support to the presence of PsA within the spondyloarthritis concept.²⁴ One recent discovery in the field of familial psoriasis involves the disease association with CARD14, which implicates cutaneous innate disease immune responses.²⁵ The extent of involvement of CARD14 in PsA awaits elucidation. Although the CARD14

mutation has an autosomal dominant pattern of inheritance, a second discovery of an autosomal recessive mutation in the IL-36 receptor antagonist has been described in both psoriasis and PsA.²⁶ This molecule is associated with pustular psoriasis and plays a pivotal role in the regulation of IL-8 and other cytokines known to be involved in psoriasis.

ENVIRONMENTAL FACTORS

Infection

The classic environmental association with psoriasis is the link with post-streptococcal tonsillitis and subsequent guttate psoriasis. This skin eruption typically affects younger patients and is associated with the presence of the HLA-Cw6 antigen. Based on restricted use of T-cell receptor expression in the tonsils and skin, a case for molecular mimicry between streptococcal and cutaneous antigens has been proposed, but the alternative possibility that the inflammatory process is driven by superantigens is likewise valid.²⁷ The importance of chronic carriage of the inciting streptococcus is also supported by data showing improvement in psoriasis when patients undergo tonsillectomy, and the degree of clinical response correlated with the decrease in frequency of peptide-reactive (streptococcal M proteins, keratin) cutaneous lymphocyte antigen (CLA+) skin-homing T cells in the circulation.²⁸ Although streptococcal infections have been associated with post-streptococcal arthritis that is totally independent of the psoriasis phenotype, no definitive evidence linking a specific infectious agent to PsA joint disease has been reported.

A role of bacterial colonization of psoriatic skin plaques and associated dysregulation of the skin barrier has also been hypothesized. Abnormal mucosal permeability of the large intestine has been reported in about 20% of PsA cases. Whether this is environmental or genetic in origin and the implications of access of bacteria or their constituent macromolecules to the circulation and the effect that this might have on expression of the skin disease remain unknown.²⁹

Trauma, obesity, and severity of psoriasis

A well-recognized association between psoriasis and trauma known as the Koebner phenomenon is widely appreciated. Koebner responses are generally greater in HLA-Cw6 positive psoriasis cases. Analogous to the skin, several studies have shown that the intriguing relationship between trauma and the presence of PsA is stronger than that between trauma and RA.³⁰ If trauma is important in PsA, the target entheses, which are sites of high mechanical stress, might exhibit signs of microdamage. Of particular relevance is that these structures often have prominent alterations, including bone microfracture, repair, and altered vascularity in normal cadaveric tissue.³¹ Intriguingly, these sites of damage may be associated with microscopic inflammatory changes.³² Thus, even in the absence of recognizable

clinical trauma, the normal physiologic responses associated with joint locomotion may lead to deep Koebner-type responses that could trigger joint inflammation.

An association between psychological stress and the development of psoriasis has been reported.³⁰ Unfortunately, accurate and scientific measurement of psychological stress remains difficult.

Obesity and severity of psoriasis have been associated with increased risk for PsA.^{33,34} In a cohort study of The Health Improvement Network (THIN), PsA incidence rates correlated with increasing body mass index. In another study performed on a cohort of patients with psoriasis, the extent of psoriasis correlated with a new diagnosis of PsA. Nail disease has also been associated with psoriasis.

IMMUNOPATHOLOGY

Any understanding of the mechanisms that underlie PsA must consider the association with psoriasis, the marked impact of local factors that account for the diversity of joint involvement, and the predilection for axial, enthesal, and tendon inflammation (Fig. 121.1a). The key sites of inflammation include not only the synovium but also the bone (osteitis), entheses (enthesitis), and tendons (dactylitis). Even though these different anatomic sites of disease were historically considered distinct unrelated entities, it has become increasingly evident in the past decade that a common anatomic biomechanical thread may connect the diverse pathologic processes.

The pattern of asymmetric arthritis has been recognized to be one of simultaneously occurring opposite phenotypes with new bone formation and bone destruction occurring in adjacent joints. These changes range from frank osteolysis (arthritis mutilans) and eccentric erosions to fluffy periostitis or frank bone erosion (see Fig. 121.1b). After the initial inflammatory insult to the joint, it appears that both osteoclastic-mediated joint damage and osteoblastic-mediated joint repair and remodeling can take place (Fig. 121.2). It is fair to say that these responses remain somewhat enigmatic beyond the fact that the local joint environment at each involved site critically influences disease expression.

Dissociation is often observed between the extent of skin and joint involvement in an individual patient. In fact, this observation has crystallized with the advent of numerous trials of biologic agents for both psoriasis and PsA, in which it became evident that the Psoriasis Area and Severity Index (PASI) score may be just minimally elevated in subjects with advanced polyarticular PsA.

Psoriatic plaque

A brief summary of the immunopathology of psoriasis is the key to setting the stage for an understanding of PsA. The events that lead to formation of the raised, scaly, erythematous plaques of psoriasis arise as a result of interactions between the innate and acquired immune responses.³⁵ Intradermal

Fig. 121.1 (a) Ray diversity in psoriatic arthritis. Note the marked differences in pathologic changes in the various rays of the hand. (b) On radiography, marked bony resorption, early “pencil-in-cup” deformities, and bony ankylosis are evident. (Reproduced with permission from the American College of Rheumatology.)

Fig. 121.2 After diffuse digital osteitis (top left), tissue repair responses may dominate and lead to new bone formation at insertions and periostitis or even bony sclerosis (bottom left). This suggests a response that is ultimately dominated by osteoblastic and mesenchymal stem cell-mediated tissue repair responses. However, after diffuse osteitis the disease processes may be dominated by osteoclastic-mediated catabolic responses, with diffuse bone destruction leading to osteolysis and other characteristic radiographic changes, including bone whittling (bottom right). (Blue bone denotes bone after resolution of the active osteitis phase. Red bone denotes the active osteitis phase.)

injection of interferon alfa (IFN- α) can precipitate psoriasis, and nucleic acids, including DNA and RNA, can lead to the upregulation of an array of “interferon signature” genes. Stressed or apoptotic keratinocytes release DNA that binds to cathelicidin LL-37, an antibacterial peptide produced by keratinocytes. This LL-37/DNA complex binds to Toll-like receptor 9 (TLR9) in the endosomes of plasmacytoid dendritic cells, which in turn promotes the release of IFN- α .³⁶ Dermal dendritic cells activated by IFN- α migrate to skin-draining lymph nodes and promote naive T-cell

differentiation to Th1 and Th17 cells. These Th1 and Th17 cells migrate to the dermis via lymphatics and blood vessels. In the dermis, INF- γ and TNF are released by Th1 cells, whereas Th17 cells produce IL-17, TNF, IL-1, and IL-22. IL-22 stimulates keratinocyte proliferation and additional cathelicidin production. Keratinocytes produce large quantities of the cytokines IL-1, IL-6, and TNF and an array of chemokines.³⁷ Dermal dendritic cells also induce autoprolieration of T cells and release IL-23, which enhances the proliferation and survival of Th17 cells. Additionally, crosstalk between

keratinocytes, fibroblasts, and endothelial cells results in tissue remodeling and deposition of matrix molecules. Marked angiogenesis is observed in the dermis where tortuous, leaky vessels form, but it remains unclear whether such changes are driving events or represent a secondary remodeling response to inflammation.

Nail disease

Although the nail is generally of limited clinical relevance to rheumatologists beyond its use in confirming the presence of PsA in a patient with inflammatory arthritis, it has nevertheless contributed greatly to a better understanding of psoriatic disease. The entheses of the distal interphalangeal joint, including the extensor tendon and lateral collateral ligaments, are intimately anchored to both the nail and adjacent periosteum.³⁸ Although the nail may be derived ectodermally, it is functionally integrated into the joint. Recent high-resolution ultrasound studies of the extensor tendons have shown that enthesopathy is observed more frequently at this site in psoriasis patients with nail disease. These subjects had no clinical arthropathy, so these findings further strengthen the link between nail disease and psoriasis. What is also intriguing is that nail disease, like joint disease, is not associated with carriage of the HLA-Cw6 antigen.³⁹

Links between skin and musculoskeletal inflammation

Epidemiologic evidence suggests that musculoskeletal involvement will develop in 13% to 25% of patients with psoriasis, but the mechanisms that underlie joint inflammation are not well understood.³⁵ Various imaging modalities, including scintigraphy, magnetic resonance imaging (MRI), and Doppler ultrasonography, have consistently demonstrated skeletal abnormalities, including periostitis, osteitis, and enthesitis, in psoriasis patients with no musculoskeletal symptoms or objective findings.⁴⁰⁻⁴² These data suggest ongoing subclinical joint inflammation in more than a third of psoriasis subjects. In a recent study, PsA was found to have developed in about 10% of patients with psoriasis over a period of 2 decades. Based on these data, it would appear that overt skeletal inflammation may not develop in the majority of patients with subclinical disease, but this finding awaits confirmation.⁴³

Several conceptual models can be envisioned to explain the links between psoriasis and joint inflammation (Fig. 121.3), and it is entirely possible that several of these mechanisms are operative in a parallel manner or in different subgroups of patients. T lymphocytes, dendritic cells, or activated monocytes may leave the skin and enter subsynovial vessels in the joint and promote inflammation. Local factors that arise in the entheses or joints, such

as trauma, stress, or infectious pathogens, could promote an innate immune response that rapidly expands to acquired immunity in the setting of pre-existing T-cell expansion in the skin and secondary lymph organs.

The skin and joint inflammation may not be linked by circulating cells but by an underlying aberrant response to injury in the skin and the joint (localized Koebner or pathergy reaction).⁴⁴ Indeed, the skin and joint entheses share some common microanatomic features, including different degrees of mechanical stress across different tissue layers and a sharp interface between vascular and nonvascular tissue.⁴⁵ Alternatively, inflammation in the gut may initiate an immune response in the skin and the joint, and the finding of subclinical bowel inflammation in up to a third of patients with PsA provides evidence for this model.⁴⁶

Synovium

One of the most intriguing aspects of joint inflammation in psoriasis is the prominent and striking vascular changes. Early studies showed changes in endothelial cells on both light and electron microscopy that consisted of swelling accompanied by inflammatory cell infiltration and marked thickening of the vessel wall.⁴⁷ Quantitative histopathologic analysis has shown that vessel numbers are higher in PsA than in RA, and arthroscopic studies have shown that PsA synovial tissue has more tortuous vascularity whereas in RA the vascular tissue takes on a more linear morphology.⁴⁸ Subsequent studies have revealed that RA tissue blood vessels can manifest linear, mixed, or tortuous patterns, although PsA synovial vasculature is almost always tortuous or bushy in appearance.⁴⁹

Histologic studies reveal an inflammatory tissue that is very similar to RA in appearance, with lining-layer hyperplasia and a subsynovial infiltrate of T cells, B cells, and monocytes. Digital image analysis of biopsied tissue has revealed that PsA tissue has a lower number of infiltrating T and plasma cells but that TNF- α , IL-1 β , IL-6, and IL-18 protein expression is similar in the two diseases. Activated T cells have been identified in the skin and joints of patients with PsA; T cells in the epidermis and joint fluid are predominantly CD8+, although more recent studies have uncovered a prominent Th17 response in psoriatic plaque.⁵⁰ Th17 cells were identified in psoriatic synovium, and mast cells in the joint tissue were also noted to express IL-17.^{51,52}

Expression of matrix metalloproteinases (MMPs), adhesion molecules, and vascular markers was also found to be comparable in PsA and RA.⁵³ In another report, PsA tissue vascularity and neutrophil infiltration were increased in PsA in comparison to RA, but antibodies to the shared epitope were observed only in RA (Fig. 121.4).⁵⁴ Most importantly, the synovial pathology of PsA resembled the features observed in spondyloarthritis more than those observed in RA. A somewhat surprising finding was the presence

Fig. 121.3 Pathogenesis of psoriatic arthritis. Infection, danger signals, or an autoimmune response leads to the overproduction of tumor necrosis factor (TNF) and other proinflammatory molecules such as interferon- α , as recently described in psoriatic plaque. It is envisioned that the response to these environmental events is strongly influenced by genetic factors. The site of the original event may take place in the skin, bone marrow, or bowel. Both the innate and the acquired immune type 1 helper T cell (Th1) and Th17 pathways are triggered, which results in the release of interleukin-23 (IL-23), IL-17, TNF, and other cytokines. In response to these cytokines and other inflammatory mediators, monocytes and T cells undergo activation and circulate to the entheses, joints, and soft tissues, where inflammation unfolds in response to local factors. G-CSF, granulocyte colony-stimulating factor; RANKL, receptor activator of nuclear factor κ B ligand.

Fig. 121.4 Distinct synovial features in spondyloarthritis (SpA) and rheumatoid arthritis (RA). Vascularity, CD163+ macrophages, and polymorphonuclear leukocytes (PMNs) were significantly increased in SpA, whereas lining-layer hyperplasia, lymphoid aggregates, CD1a+ dendritic cells, and intracellular citrullinated antibodies were higher in RA. mAb, monoclonal antibody. (From Kruithof E, Baeten D, Van den Bosch F, et al. *Histological evidence that infliximab treatment leads to downregulation of inflammation and tissue remodelling of the synovial membrane in spondyloarthropathy*. *Ann Rheum Dis* 2005;64:523-36.)

of lymphoid aggregates in the synovium that were similar in prevalence and appearance to those observed in RA tissue.⁵⁵ Taken together, the histopathologic studies indicate the presence of marked vascularity with fewer T lymphocytes but greater infiltration of neutrophils in psoriatic than in rheumatoid synovium.

Enthesis

The importance of enthesitis as a key pathologic lesion in the seronegative spondyloarthritides, including PsA, has recently been elucidated (see

Fig. 121.5 Synovial-entheseal complex of an extensor tendon (ET) in an interphalangeal joint, as seen in a sagittal section of a finger. Synovium lines the deep surface of the tendon except in the region of the sesamoid fibrocartilage (SF), which in a flexed finger is compressed against articular cartilage. EF, entheses fibrocartilage; SC, synovial cavity; SM, synovial membrane. (From McGonagle D, Tan AL, Benjamin M. *The biomechanical link between skin and joint disease in psoriasis and psoriatic arthritis: what every dermatologist needs to know*. *Ann Rheum Dis* 2008;67:1-4.)

Chapter 123). The enthesis is an organ that dissipates mechanical stress over a wide area, including the adjacent bone and soft tissues; consequently, the immunopathology associated with enthesitis is similarly distributed over a wide area. Of particular importance is that the enthesis may be closely integrated with the adjacent synovium, bursae, and fibrocartilage, which together form a structure termed a **synovial-entheseal complex** (Fig. 121.5).

The insertion point in bone is fibrocartilaginous and normally avascular, which minimizes stress and risk for injury at the sites of highest impact. Despite these anatomic adaptations, stress forces can lead to injury and microscopic inflammation in normal insertions. When compared with the synovium, the molecular basis for human enthesitis has been very difficult to study, largely because of the relative inaccessibility of the enthesis tissue. The limited histologic data on enthesitis show destruction of fibrocartilage, vascular changes, and the presence of predominantly inflammatory cells. However, imaging of acute enthesitis shows a diffuse inflammatory reaction with sparing of the avascular fibrocartilage (Fig. 121.6). This does not support the concept that autoimmunity against fibrocartilage antigens underlies the enthesitis in PsA.

Dactylitis

The pathophysiologic events that are responsible for dactylitis, a defining feature of PsA, are not well understood, but imaging studies have provided some intriguing clues.⁵⁶ MRI studies of dactylitis show flexor tenosynovitis, circumferential soft tissue inflammation, synovitis, and bone marrow edema. Of note is the fact that erosions are more commonly seen in digits with dactylitis, and joint fusion is also observed.⁵⁷ One possibility is that the diffuse tissue inflammation begins at the attachment of the capsule onto the phalanx and represents a form of enthesitis.⁵⁸ However, enthesitis does not explain the widespread tissue inflammation and the predilection for involvement of the second digit of the hand and the fourth digit of the foot. An additional hypothesis is that the process begins in the entheses but spreads to the soft tissues and bone in response to trauma and represents a deep form of the Koebner phenomenon.

PATHOLOGIC CARTILAGE RESORPTION AND ALTERED BONE REMODELING

Cartilage resorption

Loss of cartilage, manifested radiographically as joint space narrowing, is a common finding on plain radiographs of joints in patients with PsA. Based on the radiographs, it is not unexpected that matrix metalloproteinases

Fig. 121.6 Magnetic resonance image of acute psoriatic arthritis–associated Achilles enthesitis. Thickening and edema of the Achilles tendon are evident in proximity to the insertion (black arrow). This is associated with prominent inflammation in the retrocalcaneal bursa (arrowhead). The avascular cartilage at the insertion point appears black (white arrow).

(MMPs) and their specific tissue inhibitors (TIMPs) are increased in the lining and subsynovial lining cells in psoriatic joints.⁵⁹ Immunohistochemical studies have revealed that MMP-9 is upregulated in the vasculature and that MMP-1, MMP-2, and MMP-3 and the inhibitors TIMP-1 and TIMP-2 are present in the synovial lining cells. Once again, the levels of MMP-1, MMP-3, and TIMP-1 and TIMP-2 messenger RNA were similar to those observed in RA. Moreover, after therapy with anti-TNF agents, serum MMP-3 levels dropped rapidly and MMP-13 staining declined in psoriatic synovial tissue. Based on these findings, it is likely that the immunopathogenetic mechanisms that dictate cartilage destruction in psoriatic joints are shared with RA and other forms of spondyloarthritis.

Altered bone remodeling

Bone involvement in PsA is heterogeneous both between and within patients. Unlike RA, in which synovitis leads to secondary diffuse osteoporosis and periarticular erosion, and ankylosing spondylitis, in which new bone formation is characteristic; in PsA bone involvement is diverse and encompasses the features of both ankylosing spondylitis and RA. Additionally, patients with PsA are prone to the development of mutilating arthritis in the distal interphalangeal joints; synovitis, acne, palmopustular pustulosis, hyperostosis, and osteitis (SAPHO syndrome); sterile osteomyelitis; and rare variants, including palmopustular psoriasis.⁶⁰

Abnormal bone remodeling and new tissue formation, including joint ankylosis and syndesmophyte formation, typically develop at sites of soft tissue inflammation at the enthesis. The common denominator for this osseous pathology relates to the functional integration of the enthesis to bone and the complex mechanical stress patterns in the bone adjacent to fibrocartilage. Diffuse skeletal inflammation at joints, including the sacroiliac, sternoclavicular, and distal interproximal joints, thus have a unifying biomechanical basis. The essence of these diffuse skeletal pathologic processes became evident not from pathologic studies but from MRI evaluation of early PsA at a stage when the radiographic findings were still normal. Basically, every site of bone or joint involvement in PsA is associated with the presence of diffuse bone marrow edema, which histologically represents osteitis.

Based on the high prevalence of bone marrow edema in the distal interproximal joint coupled with evidence from MRI studies of RA,⁶¹ it is reasonable to speculate on an association between osteitis and subsequent joint destruction. Baseline MRI has been demonstrated to have prognostic value in predicting joint destruction in the sacroiliac joint in patients with

ankylosing spondylitis, but its ability to show arthritis mutilans awaits confirmation.

Although the precise origins of bone marrow edema and osteitis in PsA remain somewhat enigmatic, there have been some tantalizing studies from animal models. Diffuse osteitis is seen in several TNF transgenic models, and the lesions are not dependent on adaptive immunity because pathology is evident in RAG double knockout mice. Also, the earliest lesions may develop in the stromal compartment of the enthesis in TNF transgenic models. MRI and histopathologic studies of arthritic TNF transgenic mice have revealed that bone marrow edema represents expansion of monocytes into the bone marrow, which corresponds to bone marrow edema signals on MRI.⁶² Similar histologic findings from rheumatoid joints have been reported in regions that manifested bone marrow edema preoperatively.⁶³ Collectively, these models underscore the potential importance of “tissue-specific” factors that are independent of adaptive or even innate immune cells as potential drivers in the genesis of entheseal-related disease because the earliest inflammatory changes occur in stromal cells at the insertion.⁶⁴

Altered bone remodeling, captured in psoriatic radiographs as large eccentric bone erosions, “pencil-in-cup” deformities, and tuft resorption, is often accompanied by features of new bone formation manifested as periostitis and ankylosis in the peripheral joints and enthesophytes in the spine. Surgical samples of psoriatic bone and adjacent synovium have revealed large multinucleated osteoclasts in deep resorption pits at the bone-pannus junction.⁶⁵ The details of osteoclast generation are discussed in Chapter 22. Briefly, two cytokines, macrophage colony-stimulating factor (M-CSF) and receptor activator of NF- κ B ligand (RANKL), bind to RANK on the surface of osteoclast precursors (OCPs) derived from circulating CD14+ monocytes and on mature osteoclasts. This ligand-receptor interaction triggers proliferation and differentiation of OCPs and osteoclast activation, respectively. Because permissive quantities of M-CSF are present in the bone marrow microenvironment, it is likely that the relative expression of RANKL and its natural antagonist osteoprotegerin (OPG) ultimately controls osteoclastogenesis, although TNF- α can synergize with RANKL and M-CSF and potentiate osteoclast formation. Interestingly, RANKL is also expressed by infiltrating Th17 lymphocytes and by synovial fibroblastoid cells in the synovial lining of inflamed joints.⁶⁶ In psoriatic synovium, marked upregulation of RANKL protein and low expression of its antagonist OPG were detected in the adjacent synovial lining (Fig. 121.7).⁶⁵ Osteoclasts were also observed in the cutting cones traversing subchondral bone, thus indicating a bidirectional attack on bone (see Fig. 121.3). Moreover, OCPs derived from circulating CD14+ monocytes were markedly elevated in the peripheral blood of PsA patients versus healthy controls. Treatment of PsA patients with anti-TNF agents significantly decreased the level of circulating OCPs, a finding that supports a central effect of TNF in the generation of precursor formation.⁶⁷

Recent advances in osteoimmunology have provided new insight into the mechanisms that are probably involved in pathologic new bone formation. Of particular relevance was the finding that two molecules, dickkopf-1 (DKK-1) and sclerostin, can inhibit the Wnt signaling pathway, as discussed in Chapter 22.⁶⁸ Activation of the Wnt pathway results in bone formation, so the finding that sclerostin levels were low in the osteocytes of bone from patients with ankylosing spondylitis supports the view that osteoid formation, mediated through Wnt signaling, is important in spondyloarthritis.⁶⁹ Additional molecules such as transforming growth factor- β (TGF- β), also expressed in synovial tissue in patients with ankylosing spondylitis,⁷⁰ can synergize with vascular endothelial growth factor (VEGF) to induce bone formation, as shown in an animal model.⁷¹

Lories and colleagues⁷² showed that bone morphogenetic protein-2 (BMP-2) and BMP-7 are upregulated in regions of pathologic new bone formation, and of particular interest was the finding that anti-TNF therapy blocked joint inflammation but not new bone formation in the DBA/1 mouse model. Phosphorylation of Smad1 and Smad5, important molecules in the downstream BMP signaling pathway, was markedly upregulated in regions of new bone formation on a calcaneal bone biopsy sample obtained from a patient with ankylosing spondylitis. These studies provide important clues about the interactions between the Wnt signaling pathway, BMPs, TGF- β , and VEGF in pathologic new bone formation, but additional studies are needed to determine the importance of these molecules in psoriatic disease.

CYTOKINE PATHWAYS INVOLVED IN SKIN AND JOINT TISSUE INFLAMMATION

The most compelling evidence for a central role of cytokines in skin and joint diseases comes from studies that show remarkable efficacy of anti-TNF agents for both skin and joint involvement. The prevailing evidence

Fig. 121.7 Receptor activator of nuclear factor κ B ligand (RANKL) and osteoprotegerin (OPG) expression in synovium affected by psoriatic arthritis (PsA). Retrieved tissues containing synovium from patients with PsA were processed for immunohistochemistry with antibodies specific for RANKL and OPG. A representative synovial membrane from a patient with PsA stained with anti-RANKL antibody (a), anti-OPG antibody (b), secondary antibody only (c), and hematoxylin-eosin (d) are shown photographed at 20 $\times$. Of note is the very specific and intense RANKL staining by synovial lining cells and OPG staining restricted to endothelial cells below the synovial lining. (Reproduced with permission from Ritchlin CT, Haas-Smith SA, Li P, et al. Mechanisms of TNF- α - and RANKL-mediated osteoclastogenesis and bone resorption in psoriatic arthritis. *J Clin Invest* 2003;111:821-31.)

supports the concept that an imbalance in proinflammatory and antiinflammatory cytokines is a dominant factor responsible for the downstream events that result in joint destruction.⁷³ Similar to RA, the cytokines TNF and IL-1 are elevated in explanted tissues from the skin, synovial tissue, and joint fluid of patients with PsA.^{74,75} A similar pattern of cytokine production in psoriatic synovium was noted by immunohistochemistry.⁷⁶

Evidence to support the importance of TNF in PsA comes from several findings. TNF transgenic mice exhibit joint destruction similar to that observed in patients with PsA.⁷⁷ In one clinical trial, subjects with the TNF- α 308 allele, which is associated with higher levels of TNF, had more erosions than did subjects without the allele,⁷⁸ and analysis of synovial tissue in PsA subjects after treatment with TNF antagonists showed decreased vascularity, synovial lining thickness, and mononuclear inflammation.^{79,80} A central question that remains to be addressed is whether Th17 effector cells are important in the musculoskeletal inflammation and matrix destruction in PsA. The answer to this question awaits definitive histologic analysis of psoriatic synovial tissue, but reports of increased levels of circulating Th17 cells in PsA in comparison to RA, along with elevated quantities of IL-17 in the synovial fluid of patients with PsA, provides support for the presence of an activated IL-23/Th17 pathway in PsA.^{81,82} Clinical trials of agents that block different molecules in the IL-17 pathway (anti-IL-17, anti-IL-17R) have proven to be markedly effective in psoriasis,^{83,84} and several studies examining the efficacy and safety of these agents in patients with PsA are under way. Moreover, a recent phase 3 trial of ustekinumab, a molecule that blocks IL-12 and IL-23, showed efficacy in PsA.⁸⁵ Together, the data indicate that psoriatic skin and joint inflammation results from a combination of innate and acquired immune interactions with a prominent role for TNF and Th1 and Th17 cells.

PSORIATIC DISEASE

Scarpa and colleagues⁸⁶ put forth the concept of “psoriatic disease” in which psoriasis is viewed as a systemic disorder that can involve multiple different tissues and organ systems such as the gut (colitis), eye (uveitis), vasculature (atherosclerosis), cardiovascular (atherosclerosis and myocardial infarction) and endocrine systems (diabetes, metabolic syndrome), in addition to musculoskeletal structures. It has been known for some time that patients with psoriasis are considerably heavier than matched controls, and a well-designed epidemiologic study by Setty and associates⁸⁷ demonstrated that obesity is a risk factor for the development of psoriasis.

Obesity is associated with a low-grade inflammatory state, and a growing body of evidence has shown that both macrophages and T cells with a proinflammatory phenotype are present in adipose tissue. Moreover, the chronic inflammation in adipocytes may promote a systemic inflammatory response.^{88,89} In fact, the presence of low-grade inflammation in adipose tissue has the potential to activate monocytes and immunocytes, which could initiate skin inflammation via mechanisms outlined earlier.⁹⁰ These

activated cells could also home to the skin, joints, eyes, bowel, and vasculature and initiate a chronic inflammatory state that is responsible for the heterogeneous disease features observed in psoriasis.

ANIMAL MODELS OF PSORIATIC ARTHRITIS

Insight into disease pathogenesis is often derived from preclinical models, but until recently PsA models had not been identified. Over the past several years, however, a number of rodent models have provided clues regarding disease mechanisms (Table 121.2).⁹¹⁻⁹⁹ The finding that an inducible keratinocyte deletion of the transcription factors JunB and c-Jun resulted in both psoriasiform skin lesion and inflammatory erosive arthritis with periostitis has generated considerable interest because of the possible link between cutaneous inflammation and arthritis.⁹¹ After the epidermal deletion, chemokine production increased, followed by the infiltration of granulocytes and macrophages. Functional B and T cells and signaling through the TNFR1 receptor were required for the full arthritis phenotype, but psoriasiform lesions were still present in mice (albeit to a lesser extent) without lymphocytes or intact TNF signaling pathways. Thus, in this model, targeted deletion of a key keratinocyte transcription factor resulted in arthritis with several features reminiscent of PsA that was in part dependent on a functional acquired immune response.

Two murine models have been described in which prominent distal joint inflammation develops. In the first, extensive resorption of the distal phalangeal bones along with pitting and frequent nail loss with hyperkeratosis and parakeratosis spontaneously developed in transgenic mice lacking endogenous MHC class II molecules.⁹⁴ Peripheral or axial arthritis did not develop in the mice, and the skin findings were localized to the affected toes. In the second model, arthritis and nail abnormalities developed in male DBA/1 mice from different litters that were caged together.⁹⁶ These mice behaved aggressively toward each other, and it is conceivable that the joint inflammation was induced by repetitive trauma. They also manifested dacrylitis and onychopariostitis in the distal phalanx. Interestingly, these findings did not develop if the mice were reared in a germfree environment.

Two additional models of arthritis that develop spontaneously with skin and joint lesions have been described besides the erosive arthritis model that was previously mentioned in the TNF transgenic animals. Gut lesions, peripheral mild nonerosive arthritis, psoriasiform skin lesions, and alopecia without thickening or shortening of the distal joints developed in the HLA-B27/ β_2 -microglobulin transgenic rat.⁹² The mice manifested only the skin lesions when raised in a germfree environment. In addition, paw swelling, joint ankylosis, nail changes, and hair loss were noted in transgenic mice lacking β_2 -microglobulin.⁹⁷ In these mice, the frequency of disease was highly influenced by non-MHC background genes. Collectively, these models suggest that alteration of MHC expression combined with microbial interaction plays a dominant role in the pathogenesis of skin and joint disease, although the precise mechanisms remain to be elucidated. An

TABLE 121.2
Animal models of psoriatic arthritis

Author	Species	Genetic alteration	Phenotype
Zenz et al. ⁹¹	Mouse	Inducible deletion of JunB and c-Jun	Psoriasiform skin lesions, erosive arthritis, periostitis
Yanagisawa et al. ⁹²	Rat	HLA-B27/ β_2 transgene	Psoriasiform nail lesions, peripheral arthritis, gut and nail lesions
Khare et al. ⁹³	Mouse	β_2 -Microglobulin knockout	Paw swelling, joint ankylosis, nail changes
Bardos et al. ⁹⁴	Mouse	Lacks endogenous MHC class II molecules	Psoriasiform skin lesions, resorption of distal phalanges, nail changes
Rothschild et al. ⁹⁵	Baboon	None	30% of baboons exhibit radiographic changes similar to those in psoriatic arthritis
Lories et al. ⁹⁶	Mouse/DBA/1 strain—males only	None	Ankylosing enthesitis, dactylitis, onychopariostitis
Cook et al. ⁹⁷	Mouse, FVB/NCrIBR strain	Amphiregulin expression under control of INV-AR	Psoriasiform skin lesions, mild knee synovitis
Ruutu et al. ⁹⁸	SKG mouse injected with mannan or curdlan	ZAP70 mutation	Enthesitis, sacroiliitis, dactylitis, plantar fasciitis, vertebral inflammation, ileitis, unilateral uveitis
Sherlock et al. ⁹⁹	Mouse	Passive collagen-induced arthritis or IL-23 minicircle injection	Enthesitis, heart valve and aortic inflammation with bone erosion and new bone formation

IL-23, interleukin-23; MHC, major histocompatibility complex.
Modified from Ritchlin C, Fitzgerald O. Pathogenesis of psoriatic arthritis. In: Ritchlin C, Fitzgerald O, editors. *Psoriatic and reactive arthritis*. Philadelphia: Mosby; 2007.

intriguing model with cutaneous features reminiscent of psoriasis in which systemic overexpression of IL-23 leads to an enthesitis-centered inflammatory arthritis and aortic root disease has recently been reported.⁹⁹ This disease has been tentatively linked to a novel population of hitherto poorly characterized lymphocytes at the enthesitis and opens up novel ways for exploring the disease process experimentally. The new paradigm has particular translational credence since it follows the description of the genetic association with the IL-23 pathway in humans and also the successful treatment of PsA with anti-IL-23 therapies.

Features of spondyloarthritis have been noted in a variety of primate species, but psoriasiform lesions have not been reported. In baboons, the prevalence of spondyloarthritis reaches 30%.⁹⁵ The distribution of erosive disease and axial involvement in Old World primates is quite similar to that observed in PsA. Thus, these primates may be a more appropriate model for the study of disease mechanisms in spondyloarthritis, but the absence of psoriasis suggests a disease pattern different from that observed in PsA.

LESSONS FROM CLINICAL TRIALS

The availability of targeted biologic molecules allows the physician scientist to directly observe human disease rather than infer from comparatively imprecise animal models. Based on insight from these studies, the spectrum of psoriasis seems to be more dependent on innate than on adaptive immunity because blockade of the innate cytokine TNF leads to powerful suppression of disease, although new bone formation remains relatively unaffected.¹⁰⁰ Efalizumab and alefacept have shown some efficacy in the skin but much less efficacy in the joints, and indeed, efalizumab may be associated with worsening of joint disease.^{101,102} The anti-TNF agents seem to exhibit differential efficacy, and in general, higher doses are needed to control skin disease than to control joint disease. Use of the anti-P40 antibody directed against a shared subunit of the cytokines IL-12 and IL-23 for the treatment of psoriasis and PsA has proved to be extremely effective, although results in the skin are more impressive than those in the joint. Moreover, several studies examining the efficacy of agents that inhibit IL-17

and its receptor in PsA are in progress.^{83,85,103} Interestingly, IL-17 blockade has not proven to be an effective strategy in RA. Recently PDE4 inhibition with a compound called apremilast has shown promise in PsA. This second messenger inhibitor appears to have wide-ranging effects on the modulation of proinflammatory responses.

The differential efficacy of several agents in RA and PsA provide invaluable insight into disease mechanisms. For example, PsA patients show significant improvement in psoriasis and joint inflammation in PsA, but joint responses were not observed in RA.¹⁰⁴ In contrast, methotrexate, a cornerstone of treatment in RA, is considerably more effective for psoriatic skin inflammation but not for the joint disease.¹⁰⁵ Also, some agents, including the retinoids, work solely in the skin and have no value in the joints. Finally, rituximab and abatacept are effective treatments in RA patients with inadequate responses to anti-TNF agents, but they show less efficacy for PsA and do not lead to improvement of psoriasis.^{106,107} Collectively, these contrasting findings from clinical trials support the presence of divergent mechanisms underlying rheumatoid and psoriatic arthritis and the pathophysiologic pathways that lead to psoriatic skin and joint disease.

CONCLUSION

The model that the pathophysiologic processes underlying PsA can be understood as an autoimmune response to a common skin or synovial antigen is not supported by the evidence. In the case of psoriasis, the LL-37/DNA complex with the subsequent release of IFN- α represents a novel autoimmune pathway, but in PsA, immune system activation triggered by events in the local joint environment appear to play a pivotal role in the regional expression of psoriatic disease. The multiple varied interactions between microbes and musculoskeletal structures promote vascular injury and release of cytokines and initiate pathways of cell activation that lead to tissue injury. A detailed genotype-phenotype correlation in the coming years will elucidate the complex nature of psoriatic joint inflammation and ultimately lead to a better understanding of the skin and joint subsets observed in psoriatic disease.

Management of psoriatic arthritis

■ DAFNA D. GLADMAN ■ VINOD CHANDRAN

- Psoriatic arthritis is a systemic disorder that causes chronic pain, altered physical appearance, and loss of function. The clinical features are diverse, but the core manifestations are psoriasis, peripheral arthritis, axial arthritis, enthesitis, and dactylitis.
- Multicenter randomized controlled trials of psoriatic arthritis that incorporate outcome measures for the core manifestations have been performed. The data from these trials allow us to make evidence-based therapeutic choices.
- Clinical trial data support the marginal efficacy of methotrexate, sulfasalazine, leflunomide, and cyclosporine for peripheral arthritis that is unresponsive to nonsteroidal agents.
- The tumor necrosis factor antagonists (etanercept, infliximab, adalimumab, golimumab, certolizumab) have proved to be efficacious and relatively safe for the treatment of peripheral arthritis and psoriasis and inhibit structural damage. Infliximab and golimumab are efficacious for dactylitis and enthesitis.
- Ustekinumab, an antibody to the common p40 subunit of interleukin-12 and interleukin-23, is efficacious in the management of psoriasis, peripheral arthritis, enthesitis, and dactylitis.
- Potential new therapies for psoriatic arthritis include biologic agents that inhibit T lymphocytes and proinflammatory cytokines.

INTRODUCTION

Psoriatic arthritis (PsA) is an inflammatory musculoskeletal disease that affects some 30% of patients with psoriasis.¹ A number of domains have been recognized, including peripheral arthritis, skin and nail psoriasis, axial arthritis, enthesitis, and dactylitis.² Psoriatic arthritis is unique among the inflammatory forms of arthritis in that it usually follows the development of skin psoriasis. Thus, patients with psoriasis are the individuals in whom PsA is most likely to develop. Management of PsA begins with early diagnosis, followed by assessment of disease activity and damage and evaluation of therapy. Effective treatment of PsA involves therapies that have the capability of improving all these clinical domains, either by using a treatment that can benefit all domains or by using combinations of therapies that can affect all domains and be used safely together.³ Because the severity of disease in each domain will vary from patient to patient, therapy should be customized accordingly.⁴ Factors that influence the choice of treatment include patient preference regarding mode and frequency of administration, potential adverse events, contextual elements such as age and comorbid conditions, and practical issues such as medical insurance coverage. In addition to controlling the signs and symptoms, a further purpose of control of multiple-domain disease activity is to improve function and quality of life (QoL), decrease progressive structural damage in joints to avoid disability, and reduce significant comorbid conditions such as cardiovascular disease to improve life expectancy.

Although PsA had been considered a mild disease, evidence has accumulated in the past 20 years that it may be a severe form of arthritis in a significant proportion of patients. Even early in the course of the disease, at an average of 10 months from the onset of symptoms, 27% of patients had erosions, and by 2 years of follow-up, at least one erosion had developed on radiographs in 47% of patients.⁵ Thus, a majority of the patients will have erosive disease during follow-up. Predictors of the development of joint damage include previous inflammation and previous damage, both as

a global measure and in an individual joint.^{6,7} Damage accumulates over time in a linear fashion.

It is most important to identify patients with PsA early and treat them appropriately because it has been shown that patients who are identified early fare better than those identified later in the course of their disease.⁸ Identification may be made easier by some of the features of PsA, including the common occurrence of distal joint inflammation, an asymmetric distribution, the presence of axial disease, and inflammation of the entire digit (dactylitis) and at the insertion of ligaments and tendons into bone (enthesitis) (see Chapter 120). In addition, a number of screening questionnaires have been developed to identify PsA in patients with psoriasis or in the general population.⁹ However, even though these screening tools functioned very well during their initial validation, recent studies comparing the instruments in other clinics have demonstrated that they do not have as high sensitivity and specificity as previously reported.¹⁰ Further work is therefore necessary to identify the best screening tool that can be completed by patients and help primary care providers refer appropriate patients for rheumatologic assessment. Several groups are trying to identify genetic or other biomarkers that can predict the development of PsA.¹¹ Levels of high-sensitivity C-reactive protein (hsCRP), matrix metalloproteinase-3 (MMP-3), and osteoprotegerin (OPG) and the ratio of the C-propeptide of type II collagen (CPII) to the type II collagen neoepitopes Col2-3/4C long mono (C2C) (CPII/C2C) have been identified as independent biomarkers for PsA in patients with psoriasis.¹² Several HLA alleles associated with the development of PsA in patients with psoriasis have also been identified.¹³ Thus biomarkers, genetic, soluble, and cellular, together with clinical features may be used to identify patients with psoriasis in whom PsA is destined to develop.

Clinical predictive factors of a more severe course include polyarticular disease, elevated levels of acute-phase reactants, evidence of disability and erosive joint disease, and demonstration of lack of response to initial therapeutic agents.¹⁴ Historically, systemic treatments of psoriasis have not prevented the onset of PsA. It is not yet known whether current use of more effective biologic agents for psoriasis will delay or prevent the appearance of PsA.

Although this chapter focuses on pharmacotherapy for PsA, it must be recognized that optimal therapy also comprises nonpharmacotherapeutic approaches, including patient and family education about the disease process and therapy, exercise, nutrition, psychological counseling, physical and occupational therapy, and orthopedic surgery. Few studies of these modalities have been conducted for PsA *per se*, although their value and utility in the management of arthritis in general and rheumatoid arthritis (RA) specifically have been investigated extensively, from which we can extrapolate their value and utility for PsA. A key role for the rheumatology team is to serve as a central triage point for these types of therapies by working closely with dermatologists in the comanagement of patients with PsA.¹⁵ The relationship between the rheumatologist and dermatologist in the management of patients with PsA is important. In some settings, typically academic, shared rheumatology-dermatology clinics have arisen for optimal coevaluation and management of both patients with psoriasis and patients with PsA. In standard clinical practice, such shared clinics may not be practical for logistic or economic reasons, but close working relationships between rheumatologists and dermatologists characterized by shared electronic records and other documents, phone discussions, and evaluation of patients in both offices on a regular basis can facilitate optimal management from the perspective of both disciplines. In general, if the primary problem is skin disease and the arthritis is mild, the subject may be managed by a dermatologist after complete assessment by a rheumatologist. Periodic assessment by a rheumatologist in such cases would be ideal. On the other hand, if the primary problem is joint disease, the rheumatologist should

primarily manage the patient, with the dermatologist confirming the diagnosis of psoriasis and providing input if the skin disease remains inadequately controlled.

ASSESSMENT OF DISEASE ACTIVITY AND OUTCOME OF PSORIATIC ARTHRITIS

The Group for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA), working with OMERACT (Outcome Measures in Rheumatology Clinical Trials), has developed a core set of clinical domains of PsA to be assessed in clinical trials (Fig. 122.1).¹⁶ Outcome measures for these domains have generally been adapted from similar measures used for the assessment of RA, such as the American College of Rheumatology (ACR) 20/50/70 scoring system, the Health Assessment Questionnaire (HAQ), and the modified Sharp–van der Heijde radiographic score, and for the assessment of psoriasis, such as the Psoriasis Area and Severity Index (PASI), as well as more general measures, such as the 36-item Short-Form Health Survey (SF-36) (Box 122.1). These measures have been used in clinical trials and clinical registries of PsA patients and have been shown to effectively assess peripheral joint and skin symptoms and signs, function, QoL, and radiographic damage. Various measures of enthesitis, dactylitis, and spinal involvement are being used in clinical trials and registries.^{17–19} Composite disease activity measures, including the psoriatic arthritis disease activity score (PASDAS), arithmetic mean of desirability functions (AMDF), Composite Psoriatic arthritis Disease Activity Index (CPDAI) and Disease Activity for Psoriatic Arthritis (DAPSA), have recently been developed.²⁰ Determination of which measures are optimal is still at a research stage. Several studies have documented the effectiveness of ultrasonography and magnetic resonance imaging in detecting inflammation in the joints and enthesal sites of patients with PsA, as well as the extent of structural damage.²¹ As these tools become more refined and widely accessible, they will enhance our ability to diagnose PsA earlier and assess the effectiveness of therapy in treating inflammation and inhibiting the progression of joint damage both in clinical trials and in clinical practice.

Drug therapies for PsA may be divided into those that provide symptomatic relief, primarily nonsteroidal antiinflammatory drugs (NSAIDs);

traditional disease-modifying antirheumatic drugs (DMARDs); and biologic agents.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS AND GLUCOCORTICOIDS

NSAIDs are useful in the treatment of PsA and provide relief of symptoms such as pain and stiffness, although published evidence of their effect on PsA is limited.²² NSAIDs have been found to be efficacious in treating the spinal pain in ankylosing spondylitis, on which evidence it is reasonable to extrapolate efficacy in management of axial PsA. However, NSAIDs do not prevent disease progression and may worsen skin lesions. They may be used as sole therapy in treating mild PsA. NSAIDs other than naproxen, however, should be used with caution in patients with PsA because their use is associated with increased risk for cardiovascular thrombotic events and patients with PsA are already at higher risk for cardiovascular events. Naproxen, therefore, may be preferable. If the symptoms persist or if more joints become involved after adequate trials with two different NSAIDs, DMARDs should be considered.

Glucocorticoid therapy in the form of intraarticular injections of corticosteroids (triamcinolone, methylprednisolone) is often used when only one or a few joints are affected. This form of therapy has proved effective for PsA.²³ Oral corticosteroids are used occasionally for relief of symptoms in patients with polyarthritis or an inadequate response to NSAIDs and significant disability. However, glucocorticoids do not work as well for patients with PsA as they do for patients with RA. Moreover, glucocorticoids need to be used with extreme caution and a slow taper because psoriasis worsens in many instances and could occasionally evolve into more severe forms such as pustular psoriasis. Treatment with oral steroids is usually resorted to as short-term therapy until other longer-acting drugs take effect and for situations in which an entire hand is swollen. Long-term steroid therapy is associated with significant toxicity such as high blood pressure, cataracts, weight gain, diabetes, osteoporosis, and avascular necrosis of bone.

TRADITIONAL DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

A paucity of clinical trials have been conducted on treatment of PsA with traditional DMARDs.²² Systematic reviews of the efficacy and toxicity of

Fig. 122.1 This concentric circle diagram reflects the hierarchy of domains of psoriatic arthritis (PsA) that may be assessed in clinical trials. The inner circle includes the core set of domains to be assessed in all clinical trials of PsA. The second concentric circle includes the set of domains to be assessed in some but not all PsA trials. The outermost circle includes the domains on the research agenda that may or may not be included in PsA trials. CT, computed tomography; MRI, magnetic resonance imaging; PGA, physician global assessment; US, ultrasound.

BOX 122.1 PSORIATIC ARTHRITIS OUTCOME MEASURES USED IN CLINICAL TRIALS

Arthritis

- American College of Rheumatology (ACR) response criteria
- Disease Activity Score (DAS, DAS44, DAS28)
- Psoriatic arthritis response criteria (PsARC)

Radiographic

- Modified van der Heijde–Sharp

Skin

- Psoriasis Area and Severity Index (PASI)
- Target lesion score
- Physician global assessment (PGA) of psoriasis

Quality of life/function

- Short-Form 36-Item Health Survey (SF-36)
- Health Assessment Questionnaire (HAQ) Disability Index
- Dermatology Life Quality Index (DLQI)
- Functional Assessment of Chronic Illness Therapy (FACIT)—Fatigue

Enthesitis

- Leeds
- SpondyloArthritis Research Consortium Canada (SPARCC)
- Maastricht Ankylosing Spondylitis Enthesitis Score (MASES)

Dactylitis

- Presence or absence
- Leeds dactylitis score

Spine

- Assessment of SpondyloArthritis international Society (ASAS) measures

DMARDs and biologic agents for PsA have shown that treatment is more effective than placebo, though more toxic.²²

Methotrexate

Methotrexate (MTX) is one of the most commonly used systemic medications for PsA despite limited evidence of efficacy in controlled trials. Only three published randomized controlled trials (RCTs) have compared MTX with placebo. The first used parenteral MTX, and though effective, it resulted in two deaths.²⁴ The second was underpowered because only 37 patients were recruited but the sample size called for 45, and the dose given was 7.5 to 15 mg/wk. Although MTX significantly improved physician global assessment, no significant effects on tender and swollen joint scores, patient global assessment, and the erythrocyte sedimentation rate were noted.²⁵ The third was a large multicenter RCT from Britain.²⁶ Patients were randomized to receive 15 mg MTX once per week versus placebo. No evidence of response was found with use of either the PsA response criteria (PsARC) or analysis of the individual components. As in the previous trial, the only benefits of MTX were reductions in patient and assessor global scores and skin scores at 6 months. MTX has not been effective in reducing progression of joint damage. Despite these results, MTX is still considered the first-line drug in all treatment recommendations for PsA, partly because the above mentioned studies have several limitations, and thus the lack of evidence is not necessary evidence of lack of efficacy.

Patients being treated long-term with MTX must undergo regular blood monitoring (blood cell counts, liver function tests, and serum creatinine) at least every 3 months. Significant elevation of liver function test results or a decrease in blood cell counts should lead to adjustment of the dose or cessation of therapy. The occurrence of liver fibrosis and cirrhosis, even in the absence of abnormal liver function test results, seems to be more frequent in patients with psoriasis than in those with RA, as reflected in the different recommendations for liver biopsy in rheumatology and dermatology. Patients with psoriasis treated with MTX who have risk factors for liver disease, especially type 2 diabetes or obesity, are at higher risk for the development of liver fibrosis than are those without such risk factors, even when lower cumulative MTX doses are given.²⁷ These risk factors are important for nonalcoholic steatohepatitis. Thus in clinical practice it is prudent to obtain serial liver biopsy specimens after a cumulative MTX dose of 1.5 g, especially in patients with risk factors for fibrosis and cirrhosis, such as obesity, metabolic syndrome, type 2 diabetes, a history of viral hepatitis, and significant alcohol use.

Sulfasalazine

Five RCTs have evaluated sulfasalazine (SSZ) for the treatment of PsA. In the largest of these, 221 patients with PsA were treated with 2 g/day of SSZ for 36 weeks.²⁸ The PsARC developed specifically for this study showed statistically significant improvement in the treatment group (57.8% for SSZ vs. 44.6% for placebo, $P = 0.05$). However, the only individual measure within the responder index to do so was patient global assessment, and longitudinal analysis showed only a trend favoring SSZ treatment. A systematic review revealed that the effect size for SSZ was less than 0.2, the level required to confirm response.²⁹ SSZ has not been demonstrated to prevent progression of joint damage. Despite the paucity of data, SSZ is also recommended as a first-line drug for patients with PsA.

Leflunomide

The efficacy of leflunomide was evaluated in one RCT, and it was shown to have a modest benefit over placebo.³⁰ In this study of 188 patients with PsA, PsARC were achieved by 59% of leflunomide-treated patients versus 29.7% of placebo-treated patients ($P < .0001$). An ACR20 response was achieved by 36.3% and 20%, respectively ($P = .01$). A PASI75 response was seen in 17.4% and 7.8%, respectively ($P = .048$). Leflunomide was found to be an effective and well-tolerated option for PsA in daily clinical practice with beneficial effects on peripheral arthritis and other PsA manifestations, including pain, fatigue, dactylitis, and skin disease.³¹ Unfortunately, radiographs were not included in the study; therefore, the effect of leflunomide on progression of joint damage has not been studied. Monitoring of leflunomide toxicity is similar to that for MTX.

Cyclosporine

Cyclosporine (CsA) is effective in controlling psoriasis. A three-arm RCT comparing CsA 3 mg/kg/day added to standard therapy, SSZ 2 g/day added to standard therapy, and standard therapy alone showed that CsA plus

standard therapy was well tolerated and more efficacious than both standard therapy alone and standard therapy plus SSZ.³² In the most recently published RCT, CsA was compared with placebo as an add-on treatment in patients with PsA who had an incomplete response to MTX monotherapy. Significant improvement was noted at 12 months in the swollen joint count, C-reactive protein, PASI score, and synovitis as detected by high-resolution ultrasound in the group that received CsA. No difference, however, was found in the HAQ or pain scores.³³ Thus, CsA has a role in the management of PsA either on its own or as an add-on treatment with MTX. Nonetheless, it is not well tolerated, with particular concern regarding hypertension and renal dysfunction. Its effect on joint damage has not been assessed.

Small molecules

Apremilast

Apremilast is a new potent, orally active phosphodiesterase 4 inhibitor that suppresses multiple proinflammatory mediators and cytokines. A phase 2 RCT of apremilast in 204 subjects randomized to 20 mg twice daily, 40 mg daily, or placebo reported an ACR20 response in 43.5%, 35.8%, and 11.8%, respectively, at 12 weeks.³⁴ Common adverse events were nausea, diarrhea, headache, nasopharyngitis, and fatigue. Similar observations were documented in a phase 3 trial, which suggested that a dose of 30 mg twice daily may be more effective than 20 mg twice daily but may also be more toxic.

BIOLOGIC RESPONSE MODIFIERS

Management of PsA was greatly facilitated when anti-tumor necrosis factor (TNF) agents became available. Additional medications directed at T cells were also introduced primarily for the treatment of psoriasis, although two were recently withdrawn from the market. Other anticytokine therapies have been developed as well.

Tumor necrosis factor- α inhibitors

Etanercept

Etanercept is a soluble receptor for TNF that is typically administered subcutaneously at a dose of 50 mg once per week. In the placebo-controlled portion of the phase 3 trial for PsA ($n = 205$), an ACR20 response was achieved by 59% of the etanercept-treated patients versus 15% in the placebo group (42% and 41% receiving background MTX, respectively) ($P < .0001$).³⁵ Skin response, as measured by the PASI score in patients with body surface area (BSA) involvement greater than 3%, showed a 75% improvement in 23% and 3%, respectively, at 24 weeks ($P = .001$). Measures of function and QoL improved significantly. Significant inhibition of progression of joint space narrowing and erosions was shown. In the open-label extension of this study, effectiveness was maintained in joint response and skin response at 2 years, and 38% improved further to a PASI75 response.³⁶ The drug was well tolerated, with the most common adverse events being injection site reactions and infections.

The Psoriasis Randomized Etanercept Study in Subjects with Psoriatic Arthritis (PRESTA) trial assessed 752 patients with highly active PsA and psoriasis (average BSA involvement, 31%); the patients were randomized to a standard dose of etanercept approved for PsA, 50 mg/wk (group 1), versus a dose approved for psoriasis, 50 mg twice a week for 12 weeks, followed by 50 mg/wk thereafter (group 2).³⁷ ACR and enthesitis scores similarly improved in both dosage arms at 12 and 24 weeks. An ACR20 response was achieved in 61% and 72% at each time point, respectively, in group 1 and in 66% and 69% in group 2. Of patients with enthesitis as assessed by Achilles tendon and plantar fascia insertion tenderness, 65% and 66% in groups 1 and 2, respectively, had no enthesitis at week 12 and 76% and 75% had none at week 24. Thus, the increased initial dose offered no advantage for the musculoskeletal domains. Substantial improvement in the skin lesions occurred, with a PASI75 response at week 12 seen in 55% and 36% ($P < .001$) in groups 2 and 1, respectively, and 70% and 62% at week 24 ($P < .05$). When the Composite Psoriatic Disease Activity Index (CPDAI) was used to analyze the results, the twice-weekly dose demonstrated an advantage over the once-weekly dose at 12 weeks.³⁸ Thus, consideration might be given to initially higher dosing in patients with severe skin disease, followed by standard dosing, an approach commonly used for psoriasis with other biologic agents.

In a recent serial skin biopsy study of patients with psoriasis treated with etanercept, transcripts of cytokines in the type 17 helper T-cell (Th17) pathway were diminished, presumably because of decreased stimulation of interleukin-23 (IL-23) by TNE.³⁹ Traditionally, anti-TNF agents have been thought to affect Th1 pathway cells and cytokines, so these results demonstrate the immunologic crosstalk that occurs among various inflammatory

cell pathways. Another study showed that the addition of MTX to etanercept could improve skin responses over those achieved with etanercept monotherapy.⁴⁰

Infliximab

Infliximab is a chimeric monoclonal anti-TNF antibody. A phase 3 study of infliximab in 200 patients with PsA (Infliximab Multinational Psoriatic Arthritis Controlled Trial II [IMPACT II]) showed significant benefit.⁴¹ Baseline demographic and disease activity characteristics were similar to those of the etanercept phase 3 trial. At week 14, 58% of infliximab-treated patients and 11% of placebo patients achieved an ACR20 response ($P < .001$). The presence and severity of dactylitis and enthesitis improved significantly in the infliximab group. At 24 weeks, a PASI75 response was achieved by 64% of the infliximab group and 2% of the placebo group ($P < .001$). Infliximab-treated patients showed inhibition of radiographic disease progression at 24 weeks.⁴² Function and QoL improved significantly. The long-term PsA data with infliximab (up to 98 weeks in the IMPACT II study) also showed persistent benefit on PsA.⁴³

Adalimumab

Adalimumab is a fully human anti-TNF- α monoclonal antibody. The standard dose approved for PsA is 40 mg administered subcutaneously every other week. It was studied in a phase 3 study ($n = 313$), the Adalimumab Effectiveness in Psoriatic Arthritis Trial (ADEPT).⁴⁴ At 12 weeks, 58% of the patients receiving adalimumab achieved an ACR20 response versus 14% of those receiving placebo ($P < .001$). This response rate did not differ between patients taking adalimumab in combination with MTX (50% of patients) and those taking adalimumab alone, similar to observations made in the etanercept and infliximab trials. A PASI75 response was achieved by 59% in the adalimumab-treated group and by 1% in the placebo group ($P < .001$) in those evaluable for PASI scoring. Radiographic progression of disease was significantly inhibited by adalimumab.⁴⁵ Function, QoL, and fatigue measures improved significantly. A 2-year extension study showed sustained ACR and PASI responses and persistent inhibition of radiographic progression. Adalimumab also demonstrated improvement in work productivity.

Golimumab

Golimumab is a fully human, anti-TNF- α monoclonal antibody that is approved in a 50-mg once-a-month subcutaneous dose for PsA based on a study of 405 patients.⁴⁶ At the primary endpoint of 14 weeks, this dose resulted in an ACR20 response in 51% versus 9% in the placebo group ($P < .001$) and an ACR50/70 response in 30% and 12%, respectively. A PASI75 response was achieved by 40% at week 14 and by 56% at week 24 in the 109 and 102 patients with at least 3% BSA involvement who were evaluable for PASI. Of those with enthesitis, significantly more patients showed resolution with golimumab than with placebo. Nail changes also significantly improved, as did measures of physical function. These improvements were sustained at 104 weeks in an open extension phase of this trial.⁴⁷ The safety of golimumab in patients with PsA was commensurate with that of other anti-TNF agents.

Certolizumab

Certolizumab pegol, another anti-TNF- α agent, is a subcutaneously administered pegylated Fab fragment. A recent phase 2 trial for PsA demonstrated improvement in 409 patients who were randomized to either placebo, certolizumab 200 mg every 2 weeks, or certolizumab 400 mg every 4 weeks.⁴⁸ The ACR20 response rate at 12 weeks was higher in certolizumab-treated patients—58% in those treated every 2 weeks, 51.9% in those treated once a month, and 24.3% in those given placebo ($P < .001$ for both)—and response was observed as early as week 1. The PASI75 response rate at week 24 in patients with psoriasis involving 3% BSA or greater at baseline was 62.2% with 200 mg every 2 weeks and 60.5% with 400 mg every 4 weeks, as opposed to a placebo response rate of 15.1% ($P < .001$ for both).

Evidence is accumulating that cardiovascular disease develops in patients with PsA prematurely and may contribute to the early mortality seen in those with this disease.⁴⁹ Potential contributors to cardiovascular disease include inflammation-induced atherogenesis and metabolic syndrome, which has been recognized with increased frequency in patients with PsA. A recent study by Tam and colleagues⁵⁰ showed that use of TNF inhibitors for PsA was associated with a reduction in carotid intima-media thickness and correlated with a reduction in markers of inflammation but was independent of changes in lipid profiles. No studies, however, have yet demonstrated a decrease in cardiovascular mortality rates or improvement in survival in patients with PsA treated with anti-TNF agents.

In summary, anti-TNF- α medications have shown the greatest efficacy of any treatment to date for the various clinical aspects of PsA. Their efficacy

in treating joint disease activity, inhibiting structural damage, and improving function and QoL are similar, as demonstrated by a recent meta-analysis.⁵¹ These agents tend to be well tolerated, and patients generally acclimate to parenteral administration, especially when they experience significant efficacy. Safety concerns are present, such as risk for infection, but no new concerns have arisen in the PsA population when compared with the more extensively studied RA patient population. However, it should also be noted that almost 40% of the patients treated with anti-TNF agents do not achieve even an ACR20 response, thus additional medications are necessary.

OTHER BIOLOGIC AGENTS

Co-stimulatory blockade agents

Alefacept is a fully human fusion protein that blocks the interaction between lymphocyte function-associated antigen-3 (LFA-3) on antigen-presenting cells and CD2 on T cells or by attracting natural killer lymphocytes to interact with CD2 to yield apoptosis of particular T-cell clones, and it has demonstrated efficacy in a phase 2 trial of PsA.⁵² However, though approved for the treatment of psoriasis, it was withdrawn from the market by the manufacturer effective November 16, 2011. This decision was apparently driven by business needs.

Abatacept (cytotoxic T-lymphocyte antigen [CTLA] 4-Ig) is a recombinant human fusion protein that binds to the CD80/86 receptor on antigen-presenting cells, thus blocking the second signal activation of the CD28 receptor on T cells. It is administered intravenously once a month and was evaluated in a phase 2 trial for PsA. In the standard-dose arm of 10 mg/kg given intravenously monthly ($n = 40$), 48% achieved an ACR20 response as compared with 19% in the placebo arm ($P = .006$), although efficacy was greater in the subgroup not previously exposed to anti-TNF therapy.⁵³ This agent is well tolerated, with the main safety issue being risk for infection, which was comparable to the rate seen with other biologic agents. A phase 3 trial using a subcutaneous preparation of abatacept for PsA is in progress.

Anti-interleukin-12/23 agents

Both IL-12 and IL-23 are overexpressed in psoriasis plaques. IL-23 is a key cytokine that stimulates the proliferation and activation of Th17 lymphocytes, which were recently appreciated as being important inflammatory cells in a variety of inflammatory diseases. Ustekinumab, a human monoclonal antibody that inhibits receptor binding of IL-12 and IL-23, has been shown to be very efficacious in treating psoriasis. Two phase 3 trials have been reported. In PSUMMIT 1, 615 patients with active PsA who had not been treated with anti-TNF agents were randomized to placebo, 45 mg ustekinumab, or 90 mg ustekinumab. ACR20 responses at 24 weeks showed a significant benefit for drug (42.5% for 45 mg, 49% for 90 mg) in comparison to placebo treatment (22.8%). ACR50 and ACR70 responses were also significantly higher in drug-treated patients. Dactylitis and enthesitis improved, as did QoL. A PASI75 response was achieved by almost 60% of the drug-treated patients as compared with 11% of the placebo-treated patients.⁵⁴ Infections were the most common side effects. The PSUMMIT 2 trial included 312 PsA patients with active disease who had failed anti-TNF agents.⁵⁵ This trial demonstrated ACR20 responses in 44% of the drug-treated groups versus 20% in the placebo-treated arm ($P < .001$). Responses were slightly higher in patients who had not previously failed treatment with an anti-TNF agent. The PASI75 responses in these trials are not as impressive as those reported in the trials of patients with psoriasis, probably because of the fact that in psoriasis trials the baseline PASI score was much higher than in the PsA studies.

ABT-874 is another IL-12/23 inhibitor that has shown a significant and enduring skin response with monthly subcutaneous dosing and will probably be studied for treatment of PsA.

OTHER POTENTIAL TREATMENTS

A pilot trial of an anti-IL-15 compound has shown efficacy in treating PsA.⁵⁶ The IL-1 receptor antagonist anakinra has not shown significant efficacy.⁵⁷ Rituximab, an anti-CD20 agent that ablates B lymphocytes and is approved for the treatment of RA and antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, did not show a significant response in an open-label trial of 21 patients with PsA.⁵⁸

Another therapeutic approach, not aimed at inflammation but instead aimed primarily at reduction of bone erosions, is to reduce

osteoclastogenesis. Denosumab, an inhibitor of receptor activator of nuclear factor κ B (RANK) ligand, has been shown to not only improve osteoporosis but also reduce the erosion rate in RA.⁵⁹ It is anticipated that this type of approach will show utility for PsA as well, especially given the known proclivity for excess osteoclast production and activation in this disease.

TREATMENT RECOMMENDATIONS

Several treatment recommendations for PsA have been published. GRAPPA published a set of treatment recommendations for the domains of PsA.⁴ These recommendations are based on formal literature reviews of therapies for disease of the peripheral joints, spine, skin, and nails and for enthesitis and dactylitis and on discussions among GRAPPA members (rheumatologists and dermatologists) (Fig. 122.2). A treatment grid was developed (Table 122.1) in which each domain was categorized as mild, moderate, or severe based on measures of disease severity and impact on function and QoL to help the clinician in making treatment decisions. Specific treatments are recommended for each clinical domain according to the level of severity and impact while providing quality of evidence and level of agreement among the GRAPPA members surveyed. It is recommended that the most severe domain be treated accordingly while ensuring that the treatment will also be effective for other affected domains. These guidelines are currently being updated. The European League Against Rheumatism also developed treatment guidelines for the management of PsA based on a literature

review.⁶⁰ Although they recognized that PsA was a heterogeneous disease requiring multidisciplinary treatment, they did not include dermatologists in the group that developed the criteria. They did, however, recommend that dermatologists and rheumatologists collaborate in the care of patients with PsA who have significant skin involvement.

CONCLUSION

PsA is a multiple-domain disease characterized by inflammation of the peripheral joints, skin and nails, spine, entheses, and digits. Mild disease in the joints and skin can be treated with antiinflammatory agents and topical treatments. A number of systemic treatments of PsA, such as inhibitors of TNF- α , have shown significant benefit in treating more severe disease and have demonstrated an ability to control damage as assessed by radiographic progression and to improve QoL and functional status. A number of other agents that inhibit cytokine expression or block cellular interactions have either demonstrated benefit or are being tested for PsA. Observation of the effectiveness of these agents has helped elucidate the pathogenesis of PsA and psoriasis, which in turn may lead to newer effective interventions. Multimodal pharmacologic and nonpharmacologic therapy is optimal, and the rheumatologist should occupy a central role in coordinating these approaches.

A key aspect of treatment is accurate diagnosis and assessment, which facilitates the institution of appropriate therapy in a timely fashion. Because

in most patients the skin manifestations of psoriasis develop long before arthritis symptoms occur, the dermatologist or primary care physician is in an ideal position to screen for arthritis and make an early diagnosis. Through appropriate treatment and coordinated care with rheumatologists, it appears to be possible, given current therapies, to prevent progressive structural damage in those whose disease is likely to progress. Significant efforts are under way to further develop and validate outcome measures that accurately map the natural history of PsA and demonstrate the impact of increasingly

effective emerging therapies on a patient's function and QoL. International treatment recommendations have been developed to aid individualized therapeutic decision-making.

Acknowledgments

The authors would like to acknowledge the contributions of Dr. Mease, who was the author of this chapter in the previous edition.

123 Enthesopathies

■ DENNIS MCGONAGLE ■ MICHAEL BENJAMIN

- The term *enthesopathy* embraces all pathologic alterations at any enthesis. However, *enthesitis* specifically implies that there is inflammation at an attachment site.
- Anatomic and imaging studies demonstrate that the enthesis itself can be closely integrated with functionally adjacent bone, periosteum, and sometimes synovium. At the latter it forms a synovio-entheseal complex.
- Recent concepts concerning the enthesis provide a unifying biomechanical basis for all spondyloarthritis related disease.
- Although enthesitis at sites like the Achilles tendon and plantar fascia is readily apparent clinically, its recognition is difficult at inflamed synovial joints owing to soft tissue changes in associated inaccessible sites, including much of the spine. However, improvements in magnetic resonance imaging and ultrasonography have transformed our recognition of enthesitis at clinically inaccessible sites.
- The clinical features of enthesopathy vary depending on the location, severity, and underlying disease, although pain and loss of function are common.
- The traditional therapeutic spectrum includes physical modalities, analgesics, nonsteroidal antiinflammatory drugs, local injections (e.g., corticosteroids), and irradiation. There is a lack of evidence for efficacy of traditional disease-modifying antirheumatic drugs such as methotrexate and sulfasalazine in enthesitis.
- Anti-tumor necrosis factor therapy may be efficacious for isolated severe peripheral enthesitis or inflammatory polyenthesitis associated with spondyloarthritis related disease.

INTRODUCTION

I will lay sinews upon you, and cover you with flesh, and form skin over you. (Ezekiel 37:6)

This quotation, which is more than 2500 years old, amply illustrates the importance of anchoring tendons to bones as a prerequisite for recognizable body form and locomotion. The enthesis is the crucial link responsible for bridging the gap¹ between the force-generating units (muscles) and the levers responsible for moving the body (bones). Defined simply, the enthesis is a site of attachment of a tendon, ligament, or joint capsule onto bone or cartilage. Because attachment sites are ubiquitous, virtually the entire skeleton can be affected by pathologic disorders of the enthesis. Historically, entheseal disease was best recognized in large, clinically accessible tendons and ligaments, including the Achilles tendon and plantar fascia, but the advent of magnetic resonance imaging (MRI) has confirmed that enthesitis is present throughout the skeleton in early stages of spondyloarthritis and is common at clinically inaccessible sites such as the vertebral bodies.

Any pathologic alteration of an enthesis, whether traumatic, degenerative, or caused by inflammatory or metabolic diseases, is termed an *enthesopathy* (Box 123.1). If the pathologic process involves the formation of a bony spur, the latter is called an *enthesophyte*. The term *enthesitis* is restricted to inflammatory disease and, in general, refers to seronegative spondyloarthritis.

HISTORY

Although the word *enthesopathy* was first used by Niepel,² it was Ball's 1970 Heberden Oration lecture³ that primarily triggered the interest of rheumatologists. Ball initiated the important view that the enthesis is centrally affected in ankylosing spondylitis, in contrast to rheumatoid arthritis, in which it is largely synovial structures that are inflamed.³ In the following years, the primarily pathoanatomic concept of enthesitis was introduced into the clinical terminology of undefined conditions such as the syndrome of seronegative enthesopathy and arthropathy in children, in addition to a constitutive feature of spondyloarthritis as defined by the preliminary European Spondylarthropathy Study Group classification criteria.^{4,5}

The original observations on enthesitis in ankylosing spondylitis did not establish a possible causal link with synovitis or osteitis. More recently, on the basis of MRI, which shows that enthesitis is common in diseased synovial joints at clinical presentation, it has been suggested that synovitis in spondyloarthritis is secondary to entheseal inflammation—in contrast to the primary synovitis of rheumatoid arthritis.⁶ Focal insertional point inflammation or enthesitis does not explain all the pathophysiologic aspects of seronegative spondyloarthritis including osteitis, but in recent years the enthesitis concept has been developed to provide a unifying concept for disease (see later). Interestingly, although the primacy of enthesitis in seronegative spondyloarthritis has been contentious in the English literature, it has gained widespread acceptance in the French-language literature.⁷ At the present time, the cellular and molecular study of enthesitis remains problematic, owing to the difficulty in obtaining suitable clinical material and the inaccessibility of many entheses compared with synovium.

ANATOMY AND PATHOLOGY

Anatomy

The *enthesis* is defined as the site of attachment of a tendon, ligament, joint capsule, or fascia to bone. There are two major types: fibrous and fibrocartilaginous. The former are characterized by pure dense fibrous connective tissue that links the tendon or ligament to the bone, the latter by a transitional zone of fibrocartilage at the bony interface. In long bones, fibrous entheses are generally located at a considerable distance from a joint and are thus typical of tendons and ligaments attached to diaphyses. The insertions of deltoid and pronator teres muscles are good examples. In contrast, fibrocartilaginous entheses are characteristic of tendons and ligaments attached to epiphyses and apophyses, where the insertional angle of the tendon or ligament relative to the bone changes throughout the range of joint movement. They are best typified by the Achilles tendon and by the tendon of supraspinatus muscle (Fig. 123.1). It is noteworthy that disease in spondyloarthritis is virtually restricted to fibrocartilaginous entheses, and thus they alone are considered in more detail. Four zones of tissue are typically recognized at such attachment sites⁸:

1. **Dense fibrous connective tissue:** Parallel bundles of collagen fibers separated by longitudinal rows of fibroblasts or "tenocytes."
2. **Uncalcified fibrocartilage:** Fibrocartilage cells, which are commonly, although not invariably, arranged in longitudinal rows, replace the fibroblasts. These cells are associated with an extracellular matrix containing type II collagen fibers and aggrecan (Fig. 123.2).
3. **Calcified fibrocartilage:** Less cellular than its uncalcified counterpart, this zone has an extracellular matrix that is calcified. A straight interface called the *tidemark* separates calcified from uncalcified fibrocartilage and is the mechanical boundary between hard and soft tissues.

BOX 123.1 DIFFERENTIAL DIAGNOSIS OF ENTHESOPATHY

- Traumatic or degenerative disease
- Spondyloarthritis (termed *enthesitis*)
- Diffuse idiopathic skeletal hyperostosis (DISH)
- Calcium pyrophosphate dihydrate or hydroxyapatite deposition disease
- Chronic fluoride intoxication
- Chronic retinoid toxicity
- Endocrine disorders (acromegaly)

Fig. 123.1 The concept of the enthesis organ, with the Achilles tendon (AT) insertion as an example. Historically, enthesal disease was seen strictly in terms of focal inflammation at the site of tendon, ligament, or capsule attachment to bone. However, the enthesis is more than a focal insertion and has been viewed as an organ (the enthesis organ), an integrated group of tissues including the insertion site itself and the immediately adjacent bone. All these structures are covered or lined by fibrocartilage. The adjacent trabecular bone network is also an integral part of the enthesis. The colored regions represent different fibrocartilages associated with the enthesis: tan, enthesis fibrocartilage (E) at the tendon-bone junction; blue, periosteal fibrocartilage (PF) on the bony surface of the superior tuberosity (ST); and teal, sesamoid fibrocartilage (SF) lining the deep surface of the tendon. A fat pad (FP) that protrudes into the retrocalcaneal bursa (RB) is covered with synovium (red outline).

In contrast, the *tissue boundary* is the junction between calcified fibrocartilage and the underlying bone. Although this interface is equally abrupt, it is more tortuous, with the degree of irregularity varying between sites.

4. **Bone:** A bony cortex at a fibrocartilaginous enthesis barely exists, because even in a large tendon like the Achilles, the subchondral bone plate is generally little thicker than one or two trabeculae. Indeed, the cortex can be focally absent at microscopic sites. It is important to recognize, therefore, that bone at the site of an enthesis is closely integrated with adjacent trabecular (cancellous) bone, which thus

Fig. 123.2 Actual histologic section of the Achilles enthesis organ. Arrows indicate the distal part of the insertion. Many entheses throughout the body have this anatomic configuration. EF, enthesis insertion fibrocartilage. FP, fat pad; PF, periosteal fibrocartilage; RB, retrocalcaneal bursa; SF, sesamoid fibrocartilage; ST, superior tuberosity; T, trabeculae.

contributes to the anchorage of the soft tissue. Indeed, Benjamin and colleagues⁹ have compared the role of bony spicules adjacent to a tendon/ligament attachment site with that of the anchorage functions of the roots of a tree. Recognizing the mechanical integration and direct continuity of cancellous bone adjacent to an enthesis with that of the attachment site itself could help to explain why osteitis and enthesitis are frequently linked. In connection with the basic anchorage role of an enthesis, however, it should also be noted that there are complex interdigitations of bone and calcified fibrocartilage that knit them into each other, which promotes the basic function of tendon/ligament anchorage.¹⁰ There are no Sharpey fibers where fibrocartilage is present at entheses because the subchondral bone plate is too thin. Sharpey fibers are, however, a feature of fibrous entheses.

Fibrocartilage

Fibrocartilage is a dynamic tissue that develops at sites where entheses are subject to shear and compressive forces. It also has the ability to promote bone formation, as shown in histologic analyses during postnatal growth.¹¹ The gradual (rather than abrupt) bending of the soft tissues of entheses

close to joint margins, which is a consequence of matrix stiffening by proteoglycans in enthesis fibrocartilage, dissipates stress concentration at the attachment site. However, it also means that parts of the enthesis and adjacent tissues are compressed during joint traction. The idea is best understood in relation to the Achilles tendon and is the archetypal example of the enthesis organ concept (see Figs. 123.1 and 123.2).^{8,12,13} When the foot is dorsiflexed, the Achilles tendon bends gradually in the region of the fibrocartilage plug as the insertional angle at which the tendon approaches the heel is changed. Consequently, the immediately adjacent part of the tendon is compressed against the superior tuberosity of the calcaneus. Mutual compression of tendon and bone leads to the formation of a sesamoid fibrocartilage in the deep surface of the former and a periosteal fibrocartilage on the surface of the latter. Facilitating the movement of the tendon relative to the bone is a bursa (the retrocalcaneal), and the tip of the Kager fat pad moves in and out of this space with foot movements to minimize pressure changes and promote boundary lubrication.¹⁴ Basic mechanical engineering principles would suggest that a tendon that kinks under load would be more liable to failure. The enthesis itself, the sesamoid and periosteal fibrocartilage, the bursa, and the fat pad collectively comprise the Achilles enthesis organ as originally defined.⁸ Together, they all function in one way or another to reduce stress concentration at the enthesis itself. Because the deep crural fascia in the lower part of the leg effectively serves as a retinaculum to reduce bowstringing and the bending that would otherwise occur at the enthesis, it too can be considered part of the enthesis organ complex.

This concept of an enthesis organ has wide applicability, and an enthesis organ is seen at many other sites in the body.¹³ Fundamentally, the development of an enthesis organ depends on the presence of either a microscopic pulley site immediately adjacent to the enthesis itself or an enthesis that is located in a pit, that is, the adjacent bone is slightly raised in comparison. The rheumatologic significance of the enthesis organ concept is that it helps to explain why patients with enthesopathies can have symptoms that affect the immediately adjacent area rather than just the tendon/ligament/bone junction itself. Comparable biomechanical conditions that lead to fibrocartilage formation at and near entheses exist at other sites, including the regions where tendons or ligaments wrap around bony pulleys (e.g., where the peroneal tendons wrap around the lateral malleolus at the ankle) and some synovial joints (sacroiliac and sternoclavicular joints).

Entheses are often regarded as being well supplied with pain and proprioceptive receptors. However, studies of the rat Achilles tendon enthesis have shown that a healthy enthesis is aneural and that nerve fibers are restricted to neighboring tissues, for example, the epitendon and particularly the tip of the Kager fat pad that protrudes into the retrocalcaneal bursa.¹⁵ Thus, in its lack of nerve fibers, enthesis fibrocartilage parallels the articular cartilage of a synovial joint. The fibrocartilage is also avascular, and the blood supply of the enthesis is derived largely from vessels in the peritenon and adjacent bone marrow.

Related structures

Benjamin and McGonagle⁸ coined the term *functional enthesis* to refer to the sites where tendons and ligaments wrap around bony pulleys. At such locations there is *contact* between hard and soft tissues but no *anchorage* as at entheses themselves. The similar presence of compressive forces at the fibrocartilaginous enthesis insertion and the wraparound tendons leads to a comparable functional demand for fibrocartilage, and this may explain why this region also can be affected in seronegative spondyloarthritis. Essentially, a functional enthesis is exactly comparable to part of an enthesis organ, that is, the region in the latter where the sesamoid and periosteal fibrocartilages are in contact with each other yet are not physically attached.

Finally, it has been described recently that many enthesis organ cartilages, by virtue of their intraarticular locations, rely on adjacent synovium for nourishment and lubrication in a manner identical to articular cartilages in synovial joints. This particular anatomic and functional unit is an example of what has been termed a *synovio-entheseal complex* and is key to understanding why enthesitis and synovitis may be intimately linked (Fig. 123.3).^{16,17}

Histopathologic features

Chronic enthesitis is characterized histopathologically by bony erosions and destruction, with inflammatory infiltrates evident in the bone adjacent to the enthesis.¹⁸ Inflammatory cells, including T lymphocytes, and edema in the bone marrow close to fibrocartilage have been observed.¹⁹ In later disease, capsular ossification, myxoid bone marrow changes, chondroid metaplasia, and the formation of synchondroses have been reported.¹⁸ The limited histologic data for sites of acute enthesitis have shown that inflammatory changes occur, including macrophage infiltration.²⁰ There are also

Fig. 123.3 The juxtaposition of an enthesis (E) and a synovial membrane (S) at many locations has led to the introduction of the term *synovio-entheseal complex* to highlight their anatomic proximity. The figure shows how the enthesis of the extensor tendon (ET) in a finger is closely related to a synovium adjacent to the attachment of the tendon to the intermediate phalanx (IP). The synovial fluid could thus be involved in nourishing not only the articular cartilages but also the sesamoid fibrocartilage (SF) that thickens the tendon adjacent to its attachment site. It is readily appreciated that inflammation of the enthesis organ would likely be associated with adjacent synovitis. (a) Low-power view of the whole joint. (b) Higher-magnification view of the juxtaposition of the enthesis, synovium, and sesamoid fibrocartilage. JC, joint cavity; PP, proximal phalanx.

very limited data on the cytokine and growth factor milieu, and much of what are available come from studies of the sacroiliac joint, where transforming growth factor- β and tumor necrosis factor- α (TNF- α) have been reported. In fact, the only direct evidence for TNF at human entheses comes from studies in which TNF blockade leads to regression of enthesitis/osteitis as determined by MRI.²¹

The molecular basis for enthesitis was investigated in a recent study which found that bone morphogenetic protein pathway signaling and its antagonists may play a role in both human enthesitis and animal models of disease.²² Specifically, *noggin*, a bone morphogenetic protein antagonist, may ameliorate experimental disease.

Although it is difficult to obtain suitable tissue from patients with enthesitis, there have been many studies looking at “normal” cadaveric entheses. These have shown that entheses from elderly individuals have a substantial degree of microscopic damage at the attachment site itself and at the adjacent fibrocartilage.²³ These age-related changes are also associated with microscopic inflammatory changes within the enthesis and immediately adjacent synovium. It has been proposed that perturbation in tissue repair or remodeling responses in younger subjects at these sites of high mechanical stress could underlie disease in spondyloarthritis.

ENTHESITIS AND THE PATHOGENESIS OF SPONDYLOARTHRITIS

A universal hallmark of spondyloarthritis

The concept that enthesitis is the universal hallmark in spondyloarthritis, linking its diverse manifestations, is supported by fat-suppressed MRI

Fig. 123.4 Magnetic resonance image (MRI) of a patient with psoriatic arthritis who clinically had a swollen knee. On MRI, clinically unrecognized enthesitis at the semimembranosus insertion is evident (white arrow). The enthesitis is recognizable by the presence of bone edema. However, not all regions of enthesitis in synovial joints, as elsewhere, have associated bone changes, which makes synovial joint enthesitis difficult to define, even on imaging.

analysis in patients with spondyloarthritis of recent onset. Knee effusions in these patients were associated with adjacent perienthesal high signal compatible with fluid or edema and bone marrow edema maximal at enthesal insertions, in contrast to findings in rheumatoid arthritis, which were predominantly synovium based (Fig. 123.4).²⁴ Enthesitis and capsular inflammation have also been reported to be commonplace in the small joints in psoriatic arthritis but not rheumatoid arthritis.²⁵ Imaging has not shown enthesitis in every inflamed synovial joint, but conventional MRI may have limited diagnostic sensitivity for enthesitis in a joint that is already swollen.

Focal insertional inflammation such as Achilles tendinitis or plantar fasciitis does not explain all of the features of spondyloarthritis, and some investigators have rejected the primacy of enthesitis in spondyloarthritis based on data showing prominent changes in the subchondral bone well away from insertions at the sacroiliac joint.²⁶ Despite the relatively low spatial resolution of conventional MRI and its inability to show all sites of enthesitis, active enthesitis was commonly observed in advanced cases of sacroiliitis and in almost half the cases of early disease.²⁷ However, interpretation of sacroiliac joint abnormalities is based on the traditional concept of enthesitis as representing focal insertional inflammation. The enthesitis organ concept and the related idea of “functional entheses,” as outlined earlier, inextricably link enthesitis and sacroiliitis even when focal insertional inflammation is not demonstrable in the latter.

Enthesitis and osteitis

Enthesitis and osteitis have been viewed as different pathologic processes. However, imaging studies including radiography, MRI, and scintigraphy clearly demonstrate that the underlying bone forms an integral part of the enthesitis²⁸ and is often involved in the disease process in both mechanically induced and inflammatory enthesopathy. The bone cortex is no thicker than the underlying trabecular network, and indeed it may be absent locally at entheses (see Fig. 123.2). The attachment site can be viewed as being a large collection of fibrous strands “inserted” into a trabecular architecture that is analogous to chain mail, that is, deformable, yet resisting tensile and compressive load. Studies of acute peripheral enthesitis have also shown that mechanical and inflammatory disease are associated with MRI-determined bone edema and osteitis in spondyloarthritis-related inflammatory disease and that its severity is related to carriage of the HLA-B27 gene.²⁸

In the light of a better understanding of the insertion proper, it now appears that there is a unifying biomechanical basis for disease localization in spondyloarthritis that can be best understood in relationship to

Fig. 123.5 Simplified schematic synthesis of the pathophysiology of spondyloarthritis viewed from the unifying concept of enthesitis. Ultimately, enthesitis is the result of activation of nuclear factor- κ B (NF- κ B) with the induction of proinflammatory cytokines. Diverse factors, including biomechanical stress at insertions and immediately adjacent tissue, with microtrauma and healing response and the deposition of bacterial fragments, convert what would ordinarily be a healing response into a clinically recognizable inflammatory response at insertions and related structures. These factors result in innate immune activation with the presentation of hitherto undefined peptides via HLA-B27, which leads to acquired immune activation and disease expression in ankylosing spondylitis. These factors ultimately result in increased proinflammatory cytokine production. Anti-tumor necrosis factor (TNF) neutralizes these, but as soon as it is stopped, disease usually returns. IL-1, interleukin-1.

enthesitis. Fibrocartilage is a dynamic tissue that occurs at regions of compression and shear and has been found at virtually all the sites of spondyloarthritis, including the joints and aortic wall. It is thus of interest that murine models with humoral and cellular immunity to the major cartilage proteoglycan aggrecan resemble human ankylosing spondylitis¹⁹ and that T-cell reactivity against cartilage has been reported in humans.²⁹ Thus whether fibrocartilage primarily indicates sites prone to microdamage or T-cell direct immune reactivity, or both, in the pathogenesis of enthesitis awaits further study.¹²

An enthesitis-based model

The precise cause and pathophysiology of disease localization to the enthesitis and related structures in spondyloarthritis are incompletely understood, but an enthesitis-based model of disease has been developed. Small particles (0.02 to 1.1 μ m in diameter), such as bacteria, may localize to certain transitional zones, including entheses, where richly and poorly vascularized areas are juxtaposed.³⁰ Bacteria, or their constituent macromolecules, may then contribute to inflammation by mechanisms that are yet to be clearly defined.³¹

Because biomechanical stress occurs at entheses in addition to other locations involved in spondyloarthritis (aorta, lung apex, uvea), it has been suggested that such stress in the presence of microtrauma and subsequent healing, together with the deposition of bacterial products, may convert a physiologic healing response into an inflammatory response.³² Relevant features include the special vascularity of entheses, with subsequent activation of Toll-like receptors by CpG motifs, lipopolysaccharide, or bacterial heat shock protein. These may, either directly or indirectly, induce nuclear factor- κ B activation to a degree that triggers an inflammatory reaction with dendritic cell activation and T-cell costimulation, leading to HLA-B27-related immune responses. This model is presented schematically in Fig. 123.5. When this model is interpreted in light of the explosion of knowledge in relation to innate immune functioning mediated via pattern recognition receptors (including Toll-like receptors), then it is clear that bacterial structural proteins and DNA alone (without viable organisms) could incite inflammatory responses at enthesal sites. Another consequence of this model is that blocking TNF production will not address the underlying pathogenic drive to disease, hence the need for long-term therapy and the relapse observed with cessation of anti-TNF treatment.³³

Although it is difficult to prove the primacy of enthesitis-related inflammation in humans, the primacy of enthesitis in experimental model systems has been demonstrated. It is now clear that in diverse experimental inflammatory spondyloarthritis models, including TNF and interleukin-23 overexpression systems, inflammation commences at insertions.^{34,35}

TABLE 123.1**Reported frequency of clinically recognizable enthesitis in the various forms of spondyloarthritis**

Spondyloarthritis	Frequency of enthesitis (%)
Ankylosing spondylitis	25-28
Reactive arthritis	13-58
Psoriatic arthritis	20
Spondyloarthritis associated with inflammatory bowel disease	7-33
Undifferentiated spondyloarthritis	27

Data from references 36 to 40.

FEATURES

Sites of enthesitis

Peripheral enthesitis is observed in all forms of spondyloarthritis. The frequency of clinically recognizable enthesitis ranges from 13% to 60% (Table 123.1). Such clinically recognizable sites include large tendons and ligaments adjacent to joints and superficial spinal insertions. The entheses of the lower limb are involved more frequently than those of the upper limb, with plantar fasciitis, Achilles enthesitis, or both being especially common. Crucially, many sites of enthesitis, including most of those in the spine and in large joints, are clinically inaccessible, something that contributed historically to the failure to recognize the primacy of enthesitis in spondyloarthritis.

Symptoms and signs

Clinically accessible sites of enthesitis can be asymptomatic, and the enthesitis might be detectable only by ultrasound techniques, but such observations lack histologic validation.⁴¹ However, nagging pain at rest or pain on movement is the main complaint in enthesitis. The degree of pain can vary from mild to disabling. The pain is often pronounced after a period of rest, especially in the morning, and improves gradually with movement. Soft tissue swelling may be visible at superficial sites such as the Achilles tendon insertion. Physical examination of deep-seated entheses such as those on the greater trochanter may reveal tenderness and palpable swelling. The relative contribution of soft tissue inflammation versus bone inflammation to pain and disability at sites of enthesitis remains to be defined.

Clinically, peripheral enthesitis may antedate the occurrence of other spondyloarthritis-related symptoms such as inflammatory back pain or peripheral arthritis, especially in juvenile-onset forms of spondyloarthritis.⁴² However, this observation is unlikely to reflect separate phases of disease and may simply indicate the presence of unrecognized enthesitis at other sites. Clinical scoring methods for accessible superficial sites of enthesitis have been developed, but further work is needed to improve the value of these—both as a diagnostic tool and as an outcome measure.³³

Differential diagnosis

Numerous diseases can lead to the clinical presentation of enthesopathy and have to be considered as potential differential diagnoses of enthesitis related to spondyloarthritis. However, in the vast majority of cases, the diagnosis usually rests between inflammatory disease and degenerative or mechanical disease (see Box 123.1). Particular clinical suspicion is needed in the diagnostic assessment of chest wall enthesitis, because recognition will preclude unnecessary cardiac investigations, for example. A major difficulty with the differential diagnosis of enthesitis is that clinicians probably fail to consider it often enough outside the classically recognized sites such as the foot and elbow.

IMAGING

In general, the diagnosis of peripheral enthesitis is clinically based, and imaging is used mostly in the research setting or for monitoring of therapy. The major need for imaging in enthesitis is probably to facilitate a diagnosis of spondyloarthritis. The value of plain radiographs for the diagnosis of early enthesitis is debatable, because characteristic changes are usually absent in

Fig. 123.6 High-resolution magnetic resonance image for a patient with early psoriatic arthritis who had acute Achilles enthesitis at presentation. There is perienthesal high signal in the soft tissue adjacent to the enthesis and also signal within the enthesis after gadolinium administration, reflecting increased vascularity. At this stage in the disease process, the enthesis fibrocartilage appears to be relatively spared (white arrow).

early disease. With the advent of MRI and ultrasonography, the role of bone scintigraphy will likely diminish even farther.

Magnetic resonance imaging

As stated, enthesitis is difficult to recognize in the axial skeleton. MRI is becoming the method of choice for evaluating spinal polyenthesitis or early inflammatory back pain in spondyloarthritis. Recent work has shown that a baseline MRI of the sacroiliac joint can be fairly reliably used to predict the radiographic development of ankylosing spondylitis at 8 years.⁴³ Also MRI of the spine can be reliably used to differentiate between spondyloarthritis and degenerative disk disease. However, enthesal abnormalities are common in the degenerative disease category.⁴⁴ The role of MRI has taken on great importance especially now that therapies are available which powerfully suppress the inflammatory phase of enthesitis.

Various recent studies have shown that fat-suppression MRI, with or without contrast agent administration, is the most sensitive method for identifying active enthesitis at any site. MRI can show perienthesal inflammation with adjacent bone marrow edema in fat-suppressed T2-weighted sequences (Fig. 123.6). Usually investigations are required for the diagnosis of clinically unrecognized enthesitis in the spine in patients with inflammatory back pain when the presence of enthesitis-associated osteitis may be diagnostic and also useful for monitoring therapy (Fig. 123.7). Although preliminary studies are promising, the value of MRI for the diagnostic and prognostic assessment of synovial joint disease in cases of definite or suspected spondyloarthritis has not been established.²⁴

Conventional radiography

The combination of erosion and bone proliferation is the radiographic hallmark of enthesitis, but this is a comparatively late feature and of limited value for early diagnosis. In early disease during the inflammatory phase, osteopenia or erosions may be evident. Subsequently, when the repair process predominates, soft tissue calcification and bone cortex irregularities at tendon entheses are observed.⁴⁵ This can progress to enthesophytes. The relationship between inflammation, new bone formation, and bone erosion

in spondyloarthritis-associated enthesitis is incompletely understood; our current understanding is depicted in Fig. 123.8.

Ultrasonography

Ultrasound evaluation is readily applicable to demonstrating enthesitis, especially in the peripheral skeleton.⁴⁶ The ultrasound appearance is associated with loss of normal fibrillar echogenicity of the entheses, with hypoechoic thickening and edema with bone erosion or new bone formation at the insertion, or with changes in enthesal vascularity as measured by power Doppler imaging (Fig. 123.9).⁴⁷ Furthermore, ultrasonography may reveal small effusions in the adjacent bursa and guide arthrocentesis. Ultrasonography, including power Doppler techniques, may be especially useful for improved early diagnosis of clinically unrecognized peripheral enthesitis, but, as stated earlier, the difficult issue of histologic validation of ultrasound findings has not been addressed.

Fig. 123.7 Fat-suppressed magnetic resonance images of a patient with spinal enthesitis before (a) and after (b) treatment with etanercept, a tumor necrosis factor (TNF) blocker. The white arrows illustrate sites of active enthesitis. These images show that spinal involvement in ankylosing spondylitis is largely an enthesitis that should be viewed as a chronic HLA-B27-associated polyenthesitis. It also illustrates how the enthesitis-associated pathologic process is often highly responsive to anti-TNF therapy, with almost complete resolution of these changes after treatment.

MANAGEMENT

Several questions need addressing before initiation of treatment of enthesitis in spondyloarthritis.¹ Is the disease primarily inflammatory (associated with spondyloarthritis), or is it predominantly degenerative (in which inflammation may also be a feature)?² Is it isolated peripheral enthesitis, or is it part of a generalized inflammatory enthesitis such as ankylosing spondylitis? A stepwise approach to treatment of isolated peripheral enthesitis may result in remission. Refractory enthesitis, defined as the persistence of symptoms after a period of 2 years despite adequate treatment, occurs in only a minority of cases with such measures.

First-line therapy

The first-line treatment of isolated peripheral enthesitis consists of nonsteroidal antiinflammatory drugs (NSAIDs), physical therapy, and orthoses. Various NSAIDs have been shown to be effective in the treatment of the spondyloarthritides, including indomethacin, diclofenac, naproxen, piroxicam, and, most recently, meloxicam and the cyclooxygenase-2 inhibitors,

Fig. 123.9 Ultrasound image of an erosive enthesitis at the site of insertion of the right Achilles tendon. Compared with the healthy site, cortical erosions are noted. The white arrowheads indicate the sites of erosion adjacent to the periosteal fibrocartilages. (Courtesy Dr. Richard Wakefield, Department of Rheumatology, University of Leeds, United Kingdom.)

Fig. 123.8 (a) Initially, inflammatory changes are noted at attachments to bone and the adjacent bone marrow as determined by magnetic imaging and scintigraphy. (b) This progresses to bone erosions, at least in the sacroiliac joint in early disease. (c) Capsular ossification leads to peripheral bone ankylosis largely via enthesal calcification. (d) In synovial joints, including the sacroiliac joint and the hip, articular cartilage may be replaced by bony bridges leading to intraarticular ankylosis of bone. The diffuse osteitis that accompanies early enthesitis may result in the joint cartilages' being subject to an immunologic attachment from beneath the growth plate that subsequently culminates in the radiologic appearance in advanced disease.

including celecoxib. Local injections of corticosteroid should be tried in patients with enthesitis at one or a limited number of sites.

Disease-modifying therapy

Conflicting data exist with respect to the use of sulfasalazine or methotrexate. Their efficacy is not impressive, but these agents have not been used early in patients with MRI-determined severe insertional and bone disease. With the advent of anti-TNF drugs, it is likely that the role of surgery for refractory isolated peripheral enthesitis will be very limited. Severe peripheral enthesitis may respond well to anti-TNF agents.⁴⁸

Management of "secondary" enthesitis

For treatment of inflammatory polyenthesitis related to ankylosing spondylitis or psoriatic arthritis, there is no question that the advent of anti-TNF treatment represented a giant therapeutic leap. Treatment with NSAIDs, sulfasalazine, methotrexate, and, more recently, leflunomide in the case of psoriatic arthritis, may be used, especially when synovial joint swelling is evident. Thus far, only the anti-TNF drugs have been associated with regression of both spinal and appendicular skeleton enthesitis (see Fig. 123.6).

The use of bisphosphonates may also have a role in enthesitis-related osteitis, but this needs further evaluation.³³ Surgery does not appear to provide any beneficial effect in enthesitis. However, it may still be useful for the removal of large bone spurs at sites such as the plantar fascia.

A major cause of disability in ankylosing spondylitis is enthesal ossification leading to reduced spinal mobility. There is currently insufficient evidence to show that NSAIDs prevent the ligamentous and capsular calcification that accompanies enthesitis. It was hoped that the anti-TNF agents would retard spinal fusion because they lead to good suppression of enthesitis/osteitis. At the present time there is evidence that a relationship exists between the inflammatory phase of enthesitis and the likelihood of subsequent enthesal new bone formation at the same spinal segment.⁴⁹ The link between inflammation and new bone formation in enthesitis is more complex than hitherto appreciated, because both erosion formation and creation of new bone seem to be anatomically and temporally uncoupled.⁵⁰ The biggest clinical challenge at the moment is to determine whether reversing enthesal inflammation prevents enthesal new bone formation in patients who do not have preexistent spinal joint fusion.

Epidemiology and classification of systemic lupus erythematosus

■ JULIA F. SIMARD ■ KAREN H. COSTENBADER

- Systemic lupus erythematosus (SLE) primarily affects women of childbearing age.
- Several non-European groups have an increased prevalence and a more severe course of disease.
- The cause or causes of SLE, a paradigmatic disorder of immune dysfunction, remain unknown, with several environmental factors being important potential triggers for those with underlying genetic influences.
- Epidemiologic evidence has linked environmental factors, including current cigarette smoking, crystalline silica exposure, oral contraceptives, and postmenopausal hormones, with the development of SLE.
- Increased disease severity is associated with poverty, lower education level, and decreased access to medical care, as well as the presence of certain autoantibodies.

INTRODUCTION

Systemic lupus erythematosus (SLE) is an autoimmune rheumatic disease of unclear etiology characterized by autoantibody production and protean organ system manifestations. Autoantibodies in SLE are directed against intracellular targets; antinuclear antibodies (ANAs) are the most characteristic and are present in at least 95% of patients with SLE. Anti-double-stranded DNA (dsDNA), anti-Smith (anti-Sm), anti-Ro, and anti-La antibodies are less common.¹⁻³ This chapter reviews the classification of SLE, gives an overview of its descriptive epidemiology, and considers the role of both host and environmental factors in its etiology.

CLASSIFICATION OF SYSTEMIC LUPUS ERYTHEMATOSUS

Criteria for the classification of SLE were developed by the American College of Rheumatology (ACR) in 1971, with subsequent revisions in 1982 and 1997 (Table 124.1).⁴⁻⁸ These criteria aim to be optimally sensitive and specific and require the involvement of at least 4 of 11 different organ systems, but they were not intended to include all possible manifestations. These criteria were developed to define a relatively homogeneous population and allow comparability of research subjects from different settings. In 2012, the Systemic Lupus International Collaborating Clinics (SLICC) group revised the 1987 ACR criteria to require one of four criteria to be clinical and at least one to be immunologic. These new criteria, as can be seen in Table 124.1, brought back old, previously used criteria such as alopecia and

expanded on others (e.g., neurologic disease extends beyond seizures and psychosis). Their revised system also classifies individuals with lupus nephritis alone if ANA or dsDNA antibodies are present.⁸

Systemic lupus erythematosus heterogeneity and subphenotypes

The classification criteria do not distinguish between phenotypic subgroups of SLE. However, the following non-mutually exclusive clinical phenotypes of SLE have been recognized based on the co-occurrence of various clinical syndromes with specific autoantibodies:

- *Anti-dsDNA/glomerulonephritis*: Anti-dsDNA antibodies are strongly associated with severe SLE and the development and activity of glomerulonephritis.⁹
- *Anti-Ro antibodies/subacute cutaneous LE and Sjögren syndrome*: Anti-Ro antibodies (also called SSA antibodies) are directed against RNA-protein conjugates and are prevalent in many autoimmune diseases, including SLE, particularly with photosensitive rash; Sjögren syndrome/SLE overlap syndrome; subacute cutaneous lupus erythematosus (SCLE); neonatal lupus; and primary biliary cirrhosis. In SLE, anti-Ro antibodies have also been associated with cutaneous vasculitis in SLE.¹⁰ In contrast, anti-La/SSB antibodies are more strongly associated with Sjögren syndrome.¹¹ Although more than half of SCLE patients may fulfill the ACR criteria for SLE, they are probably a distinct phenotype with recognizable annular or psoriasiform photosensitive rashes, less visceral involvement, and the requirement for immunosuppressive therapy.¹²
- *Antiphospholipid antibody syndrome*: Antiphospholipid antibodies, including lupus anticoagulant, anticardiolipin antibodies, antiprothrombin antibodies, and anti- β_2 -glycoprotein I antibodies, identify SLE patients with a distinct phenotype—high risk for occlusive vasculopathy, livedo reticularis, strokes, and miscarriages—and probably a common etiology and pathogenesis.^{9,13}
- *SLE/mixed connective tissue disease overlap*: This clinically distinct syndrome is characterized by anti-U1 ribonucleoprotein antibodies; puffy hands; arthritis, which can be erosive; Raynaud phenomenon; pulmonary hypertension; and relative protection from renal disease.¹⁴

DESCRIPTIVE EPIDEMIOLOGY

Sex

SLE is predominantly a disease of women, although the excess female preponderance varies with age. Before puberty, SLE is approximately twice as common in girls. During the childbearing years, the female-to-male ratio

■ **TABLE 124.1**
Evolution of criteria classification systems for systemic lupus erythematosus*

Criterion	ACR 1971 ⁵	ACR 1982 ⁶	ACR 1997 ⁷	SLICC 2012 ⁸
Malar rash	Malar rash	Malar rash	Malar rash	Acute cutaneous rash
Discoid rash	Discoid rash	Discoid rash	Discoid rash	Chronic cutaneous rash
Raynaud phenomenon	Raynaud phenomenon			
Alopecia	Alopecia			Nonscarring alopecia
Photosensitivity	Photosensitivity	Photosensitivity	Photosensitivity	
Oral/nasal ulcers	Oral or nasal ulcers	Oral or nasal ulcers	Oral or nasal ulcers	Oral or nasal ulcers
Arthritis	Arthritis without deformity	Nonerosive arthritis in at least 2 peripheral joints	Nonerosive arthritis in at least 2 peripheral joints	Synovitis involving at least 2 joints or tenderness in at least 2 joints with at least 30 min of morning stiffness
Serositis	A. Pleurisy B. Pericarditis	A. Pleurisy B. Pericarditis	A. Pleurisy B. Pericarditis	A. Pleurisy B. Pericarditis
Renal disorder	A. Profuse proteinuria B. Cellular casts	A. Profuse proteinuria B. Cellular casts	A. Profuse proteinuria B. Cellular casts	A. Profuse proteinuria B. Red blood cell casts
Neurologic	A. Psychosis B. Convulsions	A. Psychosis B. Seizures	A. Psychosis B. Seizures	A. Psychosis B. Seizures C. Mononeuritis multiplex D. Myelitis E. Peripheral or cranial neuropathy F. Acute confusional state
Hematologic	A. Hemolytic anemia B. Leukopenia C. Thrombocytopenia	A. Hemolytic anemia B. Leukopenia C. Thrombocytopenia D. Lymphopenia	A. Hemolytic anemia B. Leukopenia C. Thrombocytopenia D. Lymphopenia	A. Hemolytic anemia B. Leukopenia C. Lymphopenia D. Thrombocytopenia
Immunologic	A. LE cells B. False-positive STS	A. LE cells B. False-positive STS C. Anti-DNA D. Anti-Sm	A. False-positive STS B. Anti-DNA C. Anti-Sm D. APS E. Lupus anticoagulant	A. Anti-DNA B. Anti-Sm C. APS C1. Lupus anticoagulant C2. False-positive rapid plasma reagin C3. at least medium anticardiolipin ab C4. anti-β ₂ -glycoprotein I D. Low complement (C3, C4, CH ₅₀) E. Direct Coombs test in absence of hemolytic anemia
Antinuclear antibody	Positive ANA	Positive ANA	Positive ANA	Positive ANA

*A minimum of four criteria is traditionally used to classify systemic lupus erythematosus.
ACR, American College of Rheumatology; ANA, antinuclear antibody; APS, antiphospholipid antibody syndrome; CH₅₀, 50% hemolyzing dose of complement; LE, lupus erythematosus; SLICC, Systemic Lupus International Collaborating Clinics; STS, serologic test for syphilis.

climbs and reaches a peak ratio of approximately 12:1. After menopause, the disproportionate incidence rates in women decline to approximately twice those in men.^{15,16} Several studies have reported that lupus in men, though rarer, is more severe than that in women.¹⁷⁻²⁰

Age

SLE may develop at any age, although its peak incidence occurs during the childbearing years (15 to 45) in women. In comparisons with adult SLE cohorts, the small populations of children and adolescents appear to have more active SLE, especially lupus nephritis, both at initial evaluation and over time.^{20,21} When compared with adults with SLE, children receive more intensive drug therapy and accrue more damage, often related to steroid toxicity.²⁰ Young age was found to be an important independent predictor of new or worsening proteinuria on routine screening, and onset of SLE during adolescence was associated with more aggressive disease and worse outcomes than was onset later in life.^{21,22} In adult women, however, onset of SLE after menopause appears to result in slightly less severe disease than premenopausal onset does.¹⁶

Ethnicity and geography

Though probably underrecognized and underdiagnosed in developing countries, SLE does occur worldwide. International studies of the incidence and prevalence of SLE are difficult to compare given differences in case

ascertainment and design. Danchenko and colleagues²³ reviewed more than 60 studies on the incidence and prevalence of SLE in the United States, Europe, Asia, and Australia from 1950 to 2006 (Fig. 124.1), and no clear north-south or east-west pattern emerged.²³ The patterns observed in the prevalence studies were similar to those in the incidence reports. Studies of Aboriginal populations in Australia and New Zealand have found a higher prevalence and incidence in these populations than in white Australians.²⁴ SLE in the United States and United Kingdom is most prevalent in those of nonwhite descent, with reports of a higher incidence and more severe disease.²⁵⁻²⁹ In addition to the higher incidence, SLE mortality rates in black females, for example, are three to four times those in white females in the United States (Fig. 124.2).³⁰⁻³² The mean age at onset of SLE is also younger in nonwhite groups,^{26,33} and disease damage accrues more quickly.³⁴

A “prevalence gradient” in those of African origin has been reported when comparing people living in sub-Saharan Africa, where the prevalence of SLE is reportedly low, with those living in Western countries, where the prevalence of SLE is reportedly higher in individuals of African origin.³⁵ The existence of such a gradient could suggest the possibility of genetic admixture or differences in environmental exposure. The lower prevalence in Africa may be due to more severe SLE, inadequate treatment reducing survival, or a lower incidence because of competing causes of death. A study in the United Kingdom revealed a high prevalence of SLE in recent immigrants from West Africa.³⁶ No comprehensive studies of the incidence of SLE have been conducted in Africa, an inherently extremely interesting but challenging population to investigate.

Fig. 124.1 Worldwide incidence of systemic lupus erythematosus (SLE). (From Danchenko N, Satia JA, Anthony MS. Epidemiology of systemic lupus erythematosus: a comparison of worldwide disease burden. *Lupus* 2006;15:308-18.)

RISK FACTORS FOR SYSTEMIC LUPUS ERYTHEMATOSUS

Complex interactions between genes and environmental exposures are probably necessary for the development of SLE. Epidemiologic studies have sought to identify potential factors that could be involved in the development of SLE in the genetically susceptible.

Hormonal/reproductive factors

Given the otherwise unexplained female excess, hormonal factors have long been of great interest in studies on the pathogenesis of SLE. Significantly lower androgen (testosterone and dehydroepiandrosterone sulfate) and higher estradiol and prolactin levels were found in women with SLE than in controls in a meta-analysis of clinical studies.³⁷ Mild or moderate hyperprolactinemia has been demonstrated in 20% to 30% of SLE patients and is associated with active disease.³⁸ Case-control studies, however, have been unable to address whether the abnormalities in hormone metabolism observed are a consequence of SLE or its treatment or are related to disease onset.

In nearly 240,000 predominantly white women monitored prospectively for up to 22 years in the Nurses' Health Study, oral contraceptives and postmenopausal hormone therapy were both associated with increased risk for incident SLE.³⁹ Furthermore, the current oral contraceptive dose of ethinyl estradiol was positively associated with SLE in women in a large study using data from the U.K. General Practice Database.⁴⁰ In both studies, risk was particularly elevated in women who recently started contraceptive use, thus suggesting an acute effect in a small subgroup of susceptible women. Data on other reproductive factors in relation to the risk for SLE have been inconsistent apart from early age at menarche, which has been found to be related to risk for SLE in several studies.^{39,41,42}

Cigarette smoking and alcohol consumption

Several,⁴³⁻⁴⁶ but not all,⁴⁷⁻⁵⁰ epidemiologic studies reported a significantly increased risk for SLE in current smokers. Seven case-control studies and two cohort studies examining smoking as a risk factor for SLE were combined in a meta-analysis, which showed an increased risk for SLE associated with current smoking (summary relative risk, 1.5; 95% confidence interval [CI], 1.1 to 2.1) but no elevated risk in past smokers.⁵¹

In a meta-analysis of six case-control studies and one cohort study investigating alcohol consumption and susceptibility to SLE, moderate alcohol intake was not significantly related to risk for SLE (summary odds ratio, 0.8; 95% CI, 0.5 to 1.2).⁵² However, one recent case-control study found that light and moderate consumption was inversely associated with SLE.⁴⁶

Fig. 124.2 Rates of death from systemic lupus erythematosus stratified by age and race. (From Centers for Disease Control [CDC]. Trends in deaths from systemic lupus erythematosus—United States, 1979-1998. *MMWR Morb Mortal Wkly Rep* 2002;51:371-4.)

Environmental contaminants

Environmental contaminants in common household products and hazardous waste sites and other relatively common exposures may affect sex hormone homeostasis and be associated with autoimmune manifestations.^{53,54} Epidemiologic studies have demonstrated that both recreational and occupational exposure to petroleum distillates, as well as to trichloroethylene and organochlorines, is related to risk for undifferentiated connective tissue disease⁵⁵ and SLE symptoms,^{56,57} but epidemiologic evidence has yet to conclusively connect trichloroethylene and SLE in humans. Two recent studies have reported that pesticide exposure, both agricultural and residential, is associated with increased risk for SLE.^{58,59}

Crystalline silica, a well-known adjuvant that leads to increased production of proinflammatory cytokines such as interleukin-1 and tumor necrosis factor, has been implicated as a trigger of SLE in both murine models and epidemiologic studies. Silica in both agricultural and urban occupational settings has been associated with increased risk for SLE.^{60,61}

Small studies and case reports in the 1990s suggested that silicone breast implants may trigger SLE and related connective tissue diseases, but no association was found in 7442 Swedish women.⁶² Implants may lead to minor reductions in some complement components and a higher prevalence of antibodies to single-stranded DNA.⁶³ Studies suggesting a role of hair dye and other cosmetics, including lipstick, remain unconfirmed.^{49,64,65}

Nutritional factors and ultraviolet light

Lower levels of vitamin D have been observed in subjects with SLE than in healthy controls, but it is unclear whether this is a cause or consequence of the disease. After onset of the disease, low vitamin D levels may be related to disease activity or to the common recommendation that people with SLE avoid sun exposure.⁶⁶ In humans, lower serum and plasma levels of antioxidants have also been reported in SLE cases both before and after diagnosis.^{67,68} No protective effect of either increased vitamin D intake or a variety of antioxidant vitamins from foods or supplements was found in women in a large prospective study.^{69,70}

Exposure to ultraviolet (UV) light may trigger SLE disease flares, including photosensitive rashes, fevers, and other systemic symptoms,⁷¹ but UV light exposure is also the main source of vitamin D production. SLE flares tend to be more common during sunnier months.⁷² In a case-control study in Sweden, a history of more than one serious sunburn before 20 years of age and a sunburn-susceptible skin type were both associated with risk for SLE.⁴⁷ Because photosensitivity secondary to SLE could be present years before diagnosis, this association is difficult to interpret. In a study that used

cumulative months of occupational sunlight exposure as a proxy for past UV exposure, no overall association with risk for SLE was observed.⁷³

Infections and immunizations

Epstein-Barr virus (EBV) seropositivity rates are much higher in adults and children with SLE than in age-matched controls.^{74,75} Many potential mechanisms involving molecular mimicry between EBV and SLE antigens have been advanced.⁷⁶ However, no data have established that EBV infection is linked to future risk for the development of SLE. In fact, in a large Danish cohort study, individuals who were tested for EBV and found to be

serologically negative had a sustained increased risk for SLE that was highest in the 1 to 4 years after testing (standardized incidence rate, 6.6; 95% CI, 3.3 to 13.2). This was probably due to testing for EBV at the initial manifestation of SLE symptoms. No association was found between EBV serologic positivity, infectious mononucleosis, or severe infectious mononucleosis requiring hospitalization and risk for the development of SLE.⁷⁷

A few case reports and case series have suggested links between SLE and pneumococcal, tetanus, *Haemophilus influenzae* type b, hepatitis B, and influenza vaccinations.^{78,79} In the Carolina SLE Study, the largest epidemiologic study to examine such relationships, there appeared to be no association between hepatitis B vaccination and SLE.⁸⁰

Preclinical features of lupus

■ JUDITH A. JAMES

- Autoantibodies and clinical features appear years before the diagnosis of systemic lupus erythematosus (SLE).
- Many patients with SLE have a time before meeting the classification criteria of the American College of Rheumatology, which is characterized by autoantibody production and an isolated clinical symptom.
- Individuals who transition from a preclinical lupus syndrome to eventually meet the SLE classification criteria often have milder clinical features and lupus-associated autoantibodies.

INTRODUCTION

Systemic lupus erythematosus (SLE) is a complex, heterogeneous disease characterized by autoantibody production and potential involvement of nearly every organ system. Consequently, diagnosis can be difficult, which has led to the development and application of classification criteria to aid in the identification of patients with SLE for clinical studies and to assist clinicians in making this diagnosis.¹⁻³ Classification as per the American College of Rheumatology (ACR) requires that a patient meet at least 4 of the 11 defined clinical or serologic parameters.^{1,2} However, new criteria devised by the SLE Inception Cohort Consortium are being proposed and require at least one clinical and one serologic criterion but allow classification based on the presence of 4 of now 17 criteria.³ Invariably, with such a heterogeneous disorder, some individuals will be seen by the health care system with some clinical features but not meeting the classification criteria for SLE. Biologically, by the time that patients receive a formal diagnosis of lupus, the majority have ongoing aggressive inflammatory processes and, oftentimes, irreversible damage (Fig. 125.1). Once these autoimmune cascades are under way, especially after standard immunomodulatory medications have been initiated, dissecting the basic concepts of disease pathogenesis can be quite difficult. Understanding which patients are at risk to transition to organ-threatening lupus is challenging, and this chapter reviews the published literature in this area.

Preclinical lupus is a broad concept that includes individuals with increased genetic risk for the development of SLE but no clinical symptoms or positive results on standard lupus serology tests; such individuals may have multiple autoantibodies and several clinical features consistent with SLE but do not meet the strict SLE classification criteria by the current ACR definition. In addition, some may argue that preclinical lupus should focus on the period before the first clinical feature develops in an individual who will subsequently be classified as having SLE, but after evidence of an immune dysregulation has been obtained so that impending pathogenic autoimmunity is imminent or ongoing. Although both considerations have merit, to be fully inclusive, this chapter will focus on preclinical lupus encompassing the entire period before classification of SLE, with a focus, when possible, on the period between the onset of detectable serologic or cellular evidence of autoimmunity and classification of SLE. Several reviews dealing with this time frame of disease have been published.⁴⁻⁶

Patients in whom a formal diagnosis of SLE is eventually made often have a period when their disease is not clear, and various investigators over the years have given these periods different names. “Latent lupus” is a term that identifies a group of patients with features consistent with SLE but who did not meet the ACR classification criteria.⁷ These individuals had to meet either one or two of the 1971 or 1982 ACR classification criteria plus any number of minor criteria, such as fever, lymphadenopathy, fatigue, low

complement, and others.⁷ Concurrently, “incomplete lupus” defines patients with fewer than four of the ACR classification criteria for SLE.⁸ In addition, “undifferentiated connective tissue disease” (UCTD) is used in a broader sense to define individuals with disease manifestations suggestive but not diagnostic of a specific connective tissue disease (CTD), which includes some individuals who may transition to SLE.⁹ As study of patients with UCTD has progressed, several groups have recognized that the individuals most likely to transition to a defined CTD usually do so early in the course of being diagnosed with UCTD. Therefore, individuals with a diagnosis of UCTD may be deemed as having early UCTD if identified within the first 1 to 3 years of the onset of symptoms. Historically, several other terms have been used in an attempt to put these patients into context, including “incipient lupus,”⁷ “lupuslike” or “probable lupus,”¹⁰ “undiagnosed connective tissue disease” (for patients with a pending evaluation), and “overlap syndromes.”¹¹ This chapter is focused on preclinical lupus and, accordingly, will concentrate on individuals who are subsequently identified as having SLE.

CLINICAL AND SEROLOGIC FEATURES OF INDIVIDUALS WHO TRANSITION TO MEET THE AMERICAN COLLEGE OF RHEUMATOLOGY CRITERIA FOR SYSTEMIC LUPUS

Historical data partnered with longitudinal serum collections

Studying preclinical autoimmunity can be quite difficult without the appropriate patient populations and associated biospecimen collections. Through a partnership with U.S. military rheumatologists and the U.S. Department of Defense Serum Repository (DoDSR), we have assembled a cohort of individuals who joined the military when clinically healthy (with normal results on a baseline screening examination, including basic laboratory evaluations such as complete blood counts, complete metabolic profiles, and urinalysis) and at some time in the future met the classification criteria for SLE. In addition to standardized extraction of ACR classification criteria, medication, and other clinical information, serial serum specimens from before and oftentimes at or after the diagnosis of SLE were also available. Using 633 serum samples from 130 patients in whom SLE developed while in the U.S. military, 115 (88%) of the 130 SLE patients were found to have at least one autoantibody present in their available, prediagnosis serum. In some patients this initial autoantibody was present up to 9.4 years (mean, 3.3 years) before SLE was diagnosed. Antinuclear, antiphospholipid, anti-Ro, and anti-La responses were present significantly earlier (mean, 3.2 years) than anti-Sm and anti-nRNP responses (1.2 years; $P = .005$), whereas anti-dsDNA appeared 2.2 years before diagnosis. Anti-ribosomal P and anti-C1q were detectable on average 1.1 and 1.4 years before classification, respectively.^{12,13} Of the patients who had at least two positive samples, one within 6 months of diagnosis and the second more than 6 months before diagnosis, 19 of 26 (73%) had increases in their anti-dsDNA levels (mean, 743 units; SEM, 212 units) within 6 months of diagnosis; levels detected in samples that were taken more than 6 months before diagnosis were lower (mean, 227 units; SEM, 37 units; $P = .018$).¹⁴ Thus, autoantibodies were normally present in SLE patients before being classified as having SLE, occurred at different time points in linked subsets, and had increased levels before diagnosis. Overall, common SLE autoantibodies gradually accrued until the time of diagnosis and then reached a plateau.

Recent technologic advances have produced a multiplexed, bead-based method to test for the presence of autoantibodies directed against the specific protein antigens 60-kDa Ro, 52-kDa Ro, La, Sm/nRNP, nRNP, nRNP

70K, nRNP A, chromatin, dsDNA, Jo-1, Scl-70, centromere B, and ribosomal P. Of these 114 patients, 33 (29%) initially had a single detectable autoantibody specificity and others had multiple specificities in their first autoantibody-positive sample. Although the target varied in these 33 patients, anti-60-kDa Ro was the most common initial antibody recognized. Antibodies to nRNP A, dsDNA, and La were also commonly found as the single, initial autoantibody.¹³ Some protein targets within linked autoantibody subsets were usually targeted first: nRNP A before or concomitant with nRNP 70K and 60-kDa Ro before or concomitant with 52-kDa Ro. Others occurred with almost equal frequency; anti-Sm and anti-nRNP preceded each other equally but commonly occurred simultaneously or closer together than we could assess from the DoDSR samples. Understanding these early responses may provide the key to identifying early diagnostic markers and developing directed tolerogens for early disease, as well as to discovering potential environmental triggers of this disorder.

Several case reports have documented the onset of antiphospholipid (aPL) syndrome preceding the diagnosis of SLE by years. However, little was known about the actual prevalence and onset of aPL syndrome in patients before the diagnosis of SLE. Sera from the DoDSR were used to evaluate the temporal relationship of aPL antibodies and clinical SLE classification.¹⁵ A total of 24 cases (18.5%) were positive for IgG or IgM aPL antibodies before the diagnosis of SLE. Anticardiolipin antibodies (aCL) appeared from 7.6 years before the diagnosis of SLE to within the same month as the diagnosis of SLE (mean, 3.0 years before SLE classification). In addition, the presence of aCL before clinical classification was associated

with a more severe disease outcome. These patients eventually met an average of 6.1 of the 11 SLE classification criteria as compared with 4.9 criteria for other patients ($P < .001$). The early aCL-positive population also more frequently had renal disease, central nervous system (CNS) disease, thrombocytopenia, and clotting events. In this population, aCL preceded the initial thrombotic events by a mean of 3.1 years.¹⁵

Comparison of the onset of symptoms to the onset of lupus autoimmunity identified 104 patients (80%) who had at least one clinical criterion present before classification.¹³ Discoid rash and seizures had the earliest mean onset times: 1.74 and 1.70 years before diagnosis. Even though the initial clinical findings varied widely between patients, the most common early symptom was arthritis, which occurred in 57 of 104 (55%) individuals with symptoms before the diagnosis of SLE (Fig. 125.2). Males were significantly more likely to have renal involvement as a first manifestation ($\chi^2 = 9.24$; $P = .003$). Since arthritis was the most common initial symptom, patient samples were analyzed for IgG rheumatoid factor (RF) to determine whether RF preceded the onset of arthritis. Of the 130 patients, 17 (13%) were found to have RF, and inflammatory arthritis eventually developed in 16 of the RF-positive patients. RF preceded the development of arthritis in 15 of these 16 cases (z value = 10.2; $P < .0001$), and RF was present on average 2.1 years before the first documented arthritis symptom. ACR-defined renal disease developed in 38 (48%) of the 80 patients who were positive for anti-dsDNA ($P = .05$).¹³ Of these 38 patients, 35 (92%) had anti-dsDNA antibodies before or concurrently with the development of ACR-defined renal disease (z value = 13.3; $P < .0001$). However, in three

TABLE 125.1
Summary table of studies with patients who transitioned to the American College of Rheumatology classification of systemic lupus from a previously identified preclinical state

Year	Reference	Patient population	No. with transition to SLE (%)	Predictors of transition	Follow-up (yr)
1989	Ganczarczyk et al ⁷	Latent lupus (1-2 of ARA 71 or 82), additional minor criteria	7 of 22 (31.8)	No predictors	8 (5-15)
1996	Calvo-Alen et al ²³	Started with 213 with eUCTD (symptoms for less than 1 yr) and had complete 5-yr data on 143	18 of 143 (12.6)	Predictors: discoid lupus, serositis, ANA homogeneous, and anti-Sm by precipitation	5 (1-5)
1997	Mestanza-Peralta et al ²⁸	ITP (splenectomy)	14 of 115 (12.2)	No clear predictors; arthritis, serositis, autoantibodies develop	7.2 (0.08-32.8)
1997	Zimmerman et al ²⁹	ITP (pediatric)	5 of 87 (5.75)	Multiple autoantibodies (dsDNA, aPL, plus others) increased risk for transition	5.5 (1-15)
1998	Danieli et al ²⁴	eUCTD, 84 patients	7 of 33 (21.2)	Fever and anti-DNA antibodies	5 (1-5)
1998	Mosca et al ²⁵	UCTD (1 autoantibody and 1 clinical feature)	12 of 91 (13.2)	Multiple autoantibodies; less sicca, Raynaud phenomenon, and photosensitivity	3 (1-8)
2000	Belfiore et al ³⁰	UCTD	5 of 57 (8.77)	Anti-60 kDa alone associated with transition	5 (1-23)
2001	Cavazzana et al ²⁷	UCTD (retrospective study)	45 of 148 (30.4)	Anti-dsDNA antibodies	5 (1-9)
2004	Ståhl Hallengren et al ⁵¹	ILE (positive ANA and at least 1 ACR clinical criterion)	16 of 28 (57.1)	Malar rash and anticardiolipin antibodies	5.3 (1-10)
2010	Lastrup et al ³²	ILE	7 of 26 (26.9)	Mild disease, absence of renal and CNS involvement	8 (1-8)
2012	Olsen et al ³⁶	ILE	3 of 22 (13.6)	Risk score of female, age <40, and select autoantibody responses	2.4 (0.5-6.5)

ANA, antinuclear antibody; aPL, antiphospholipid; ARA, American Rheumatism Association; CNS, central nervous system; dsDNA, double-stranded DNA; eUCTD, early undifferentiated connective tissue disease; ILE, incomplete lupus; ITP, idiopathic thrombocytopenia purpura; SLE, systemic lupus erythematosus; UCTD, undifferentiated connective tissue disease.

patients, evidence of an ACR-defined renal disorder appeared before anti-dsDNA was detectable. These data support associations between lupus-specific autoantibodies and specific disease symptoms; however, how the concentration, specificity, and affinity of these autoantibodies change during the preclinical period is not yet known.

The DoDSR has also served as a way to initially examine whether early intervention with antimalarial agents, such as chloroquine or hydroxychloroquine (HCQ), could influence the progression of lupus autoimmunity or clinical onset of disease. Of the 130 patients in the initial cohort, 26 received HCQ before meeting four ACR criteria. Patients treated with HCQ before diagnosis had a longer ($P = .018$) time between the onset of the first clinical symptom and SLE classification than did matched, non-HCQ-treated SLE patients (median times of 1.08 versus 0.29 year, respectively). Patients treated with prednisone before being classified as having SLE also progressed more slowly to meet the classification criteria than did matched non-prednisone-treated SLE patients ($P = .011$). Those who received both HCQ and prednisone ($n = 13$) had a significantly longer time between the initial clinical symptoms and SLE classification than did patients treated with only prednisone ($n = 14$) before diagnosis ($P = .03$). Differences in median times between patients who received nonsteroidal antiinflammatory drugs (NSAIDs) before diagnosis and patients who did not receive NSAIDs were not significant ($P = .19$). Interestingly, patients treated with HCQ also had a lower rate of autoantibody accumulation and a decreased number of autoantibody specificities at and after diagnosis.¹⁶ These findings suggest that early identification of individuals at increased risk for the development of SLE is meaningful since interventions with low-toxicity immunomodulatory agents offer advantages early in the course of autoimmune events.

Retrospective chart review of inception cohorts

Evaluation of preclassification events by retrospective chart review has provided additional insight into the early clinical features of lupus. As one example, a multicenter study of 513 Danish patients with SLE published in 1998 evaluated early clinical manifestations by detailed retrospective chart review. Discoid rash (50 patients [10%], -4.5 years before classification), arthritis (259 patients [50%], -3.0 years), photosensitivity (136 [27%], -1.8 years), malar rash (162 [32%], -1.4 years), and Raynaud phenomenon (78 [15%], -1.7 years) were some of the earliest clinical manifestations found before the classification of SLE.¹⁷

Transition of latent lupus to systemic lupus

In 1989 the Toronto Lupus Group identified a group of 98 individuals who met either one or two of the 1971 or 1982 ACR classification criteria plus any number of minor criteria, such as fever, lymphadenopathy, fatigue, or low complement. Of these individuals, SLE was diagnosed in six within the first year of follow-up, and they were excluded. Also, 70 additional patients had been observed for less than 5 years, which left 22 patients meeting their definition of latent lupus with at least 5 years of follow-up. Of these 22 individuals, 7 (32%) accrued additional criteria leading to the classification of SLE (Table 125.1). No strong associations with baseline clinical or serologic findings were present that could differentiate patients who would transition to SLE during follow-up from those who had persistent latent lupus⁷; however, patients who transitioned appeared to have milder symptoms than did those of their standard SLE cohort (e.g., no renal or CNS involvement).

Transition of patients with undifferentiated connective tissue disease to systemic lupus

One important issue is whether patients with UCTD transition to SLE and, if so, whether those with UCTD at the highest risk of transitioning can be identified by clinical, demographic, or serologic features. Studies of patients with UCTD over the past 2 decades have led to improved recognition of those at the highest risk for the development of defined CTDs, such as SLE, as opposed to the approximately 75% of UCTD patients who will not.^{9,18-23} To this, one may add a 1991 multi-institutional cohort study of 213 U.S.-based early UCTD patients (within 1 year of identification), which has helped detect patients in this group who would transition to SLE. After 5 years of follow-up, 67% had transitioned to a specific CTD (143 individuals), with 18 of these individuals transitioning to SLE (18 of 213, or 8.5% of the original cohort).²² In a univariate analysis, individuals who were more likely to transition to SLE were younger and black, in addition to having symptoms or serologic findings of alopecia, serositis, discoid lesions, anti-dsDNA, anti-Sm, positive antinuclear antibody (ANA) with a homogeneous pattern, Coombs positivity, or a false-positive syphilis test result (which is now recognized to probably represent aPL responses). Regression modeling retained discoid lesions, serositis, anti-Sm (by precipitin), and ANA homogeneous patterns as the best predictors of UCTD patients who would evolve to SLE²² (see Table 125.1).

In a study from a hospital in rural Italy, 84 patients with early UCTD (symptom onset within the past year) were observed for 5 years for transition to another CTD.²⁴ The baseline characteristics of these individuals were typical of UCTD patients and included Raynaud phenomenon (54%), arthralgia (51%), arthritis (23%), fever (23%), and asthenia (16%). A defined CTD developed in 33 of the 84 patients (39%), including SLE in 7 (8.3% of the original cohort). Univariate analysis showed anti-dsDNA, aCL, and fever to correlate with subsequent SLE disease classification; aCL responses, however, were not significant in the multivariate analysis.²⁴ A 5-year follow-up study of 165 Italian UCTD patients with symptoms for less than 2 years showed 10 individuals transitioning to a defined CTD, including 5 with SLE.²⁵

Another study of UCTD patients (at least one clinical feature and autoantibody positive) from Pisa, Italy, were reported with 1 year²⁶ and 5 years²⁷ of follow-up. After 5 years, 83 UCTD patients were available for inclusion, and 18 had transitioned to SLE (22%). The presence of aCL responses and the presence of multiple autoantibody specificities were associated with subsequent SLE classification (see Table 125.1). In another study from Milano, Italy, published in 2001, 148 patients with UCTD were retrospectively evaluated. Of these, a well-defined CTD developed in 36 (average of 4.5 years of follow-up), including 11 with SLE (7.4% of the original cohort). Anti-dsDNA again predicted the evolution to SLE classification.²⁷

A large group of 665 UCTD patients were identified, recruited, and observed in Hungary between 1994 and 1999, with the exclusion of 50 individuals with only Raynaud phenomenon and 31 with only polyarthritis.³³ Of these 665 individuals, a defined CTD developed in 230, including 28 with SLE. Fever, serositis, photosensitivity, ANA homogeneous pattern, and anti-dsDNA were each associated with the subsequent development of SLE. Patients with SLE and a documented UCTD period were more likely to be older and have more serositis, less skin rash, less renal involvement, and less hemolytic anemia than were SLE patients from this same group without a documented UCTD period.³³ In a study from Portugal, 184 patients with UCTD were identified on the basis of positive ANA and at least one clinical feature of CTD. Of these, 74 had a lupus-like disease (based on clinical features and autoantibody profiles); however, longer-term follow-up of these individuals is not readily available. Finally, a study from the Netherlands investigated ANA-positive individuals referred for evaluation in a rheumatology clinic (excluding anti-dsDNA-positive individuals) and monitored them prospectively. Of these 65 individuals with a mean follow-up of 9.3 years, a specific rheumatic disease diagnosis could be established in 38, including 6 who transitioned to SLE after a median of 2.2 years.³⁴

Although the vast majority of patients with UCTD remain in the UCTD category (see Table 125.1), some information about preclinical lupus can be gleaned from the cumulative transition of 93 individuals to an SLE classification in these populations. An ANA homogeneous pattern and individuals positive for anti-dsDNA, anti-Sm, and aCL are at higher risk for transitioning to SLE, as are individuals with multiple autoreactivities or multiple clinical features. Please see reviews¹⁸⁻²⁰ for more detailed information.

Transition of incomplete lupus erythematosus to systemic lupus

Another series of studies observed groups of patients termed as having incomplete lupus erythematosus (ILE) for evaluation and development of predictors to identify those in whom SLE will subsequently develop. Based on the somewhat overlapping definitions, a subset of UCTD patients could also be termed as having ILE; however, these sets of data are delineated in this chapter based on the designation used in the respective manuscript. One of the first papers to discuss ILE and to study these patients was published in 1989.⁸ In this study, 38 patients with ILE (defined as meeting at least one and up to three ACR SLE classification criteria) were monitored for an average of 1.6 years, and only 2 patients transitioned to the SLE classification.⁸ Another study from Puerto Rico used a similar ILE definition and observed 87 patients for a mean of 2.2 years who met at least one ACR clinical criterion for SLE. Of these 87 individuals, 8 transitioned to SLE in the follow-up period. Patients who evolved to SLE were more likely to have photosensitivity, malar rash, oral ulcerations, anti-dsDNA responses, and low levels of C3.³⁵ CNS, renal, and serositis ACR criteria were quite infrequent in the ILE patients who transitioned to SLE in this cohort.

Another large collaborative study enrolled 122 patients in whom ILE had been diagnosed less than 1 year earlier (autoantibody positive with at least one ACR SLE clinical criterion) from 10 centers. On enrollment, 22 of these individuals were classified as having SLE. The remaining 100 ILE patients were evaluated annually for at least 3 years, and 3 of them transitioned to SLE. The most common baseline features in these ILE patients were leukopenia, fatigue, arthritis, and mucocutaneous involvement. The number of individuals who transitioned was insufficient to identify predictors of the

development of SLE. In a Swedish study of 28 ILE patients (fewer than four ACR criteria) with an average follow-up of 5.3 years, 16 individuals transitioned to the SLE classification (57%). Malar rash, aCL responses, and thrombocytopenia were all increased in the subset of individuals who transitioned to SLE.³⁶ An 8-year prospective study of 37 ILE patients (autoantibody positive with at least two but less than four ACR criteria) demonstrated that 7 ILE patients (19%) transitioned to the SLE classification (3.64 per 100 person-years of follow-up).³⁷

Finally, a U.S.-based study monitored 22 ILE patients (fewer than four ACR criteria) for an average of 2.4 years and showed that 3 of the 22 (14%) transitioned to the SLE classification. All patients who transitioned were female and younger and had increases in IgG autoreactivity. Individuals who transitioned were more likely to have autoantibodies against proliferating cell nuclear antigen, β_2 -microglobulin, C1q, and hemocyanin at baseline than were those who remained ILE, and those who transitioned had significant increases in IgG responses against La and liver cytosol type 1. A quantitative risk score based on female gender, baseline ANA higher than 200 units, baseline age younger than 40 years, increase in overall IgG autoreactivity on an autoantigen array, and presence of IgG responses against seven baseline autoantigens was devised and yielded strong differentiation between ILE patients who transitioned to the SLE classification and those who remained ILE ($P = 1.38 \times 10^{-7}$).³⁸ Although nearly all the longitudinal studies of ILE patients found that individuals who transitioned to the SLE classification had relatively mild SLE without major organ involvement, nephritis and serositis developed in one of the patients in the Olsen study,³⁶ and a case report of transition of an ILE patient to severe SLE with major organ vasculitis was reported.³⁸ A summary of highlights from these studies is provided in Table 125.1. In total, an interim summary of the many studies on ILE is that approximately 10% of these patients will transition to SLE, oftentimes with a milder course of disease that lacks nephritis, vasculitis, or major CNS involvement.

New studies are focusing on serologic biomarkers, which are common in patients with incomplete lupus as opposed to patients classified as having SLE and healthy controls. Using a microarray-based platform with 70 autoantigens, elevated levels of at least one IgG autoantibody were detected in 19% of ILE patients versus 26% of SLE patients (both of which were higher than in unaffected family members of lupus patients or healthy controls). In addition, IgG-to-IgM autoantibody ratios showed a stepwise increase from healthy controls to ILE to SLE in this study.³⁹ A newer study from the same group compared 27 SLE patients, 24 ILE patients, 22 unaffected first-degree relatives, and 11 unaffected, unrelated healthy controls. A set of 63 interferon genes were upregulated in 83% of the SLE patients and in 50% of the ILE patients versus no interferon-high individuals in the two control groups. In both the SLE and ILE patients, interferon-high status was associated with a subset of IgG autoantibody responses primarily targeted against DNA- or RNA-binding proteins. Additional longitudinal evaluation of ILE patients, both in the interferon-high and in the interferon-low groups, is necessary to see whether ILE patients with elevated interferon signatures are at higher risk for transition to SLE.⁴⁰

Transition of patients with another systemic autoimmune disease to systemic lupus

A small subset of SLE patients are initially seen with another systemic autoimmune disease and then subsequently transition to SLE meeting the ACR disease classification criteria. A few examples of these disorders include idiopathic thrombocytopenia purpura (ITP), thrombotic thrombocytopenia purpura (TTP), aPL syndrome, discoid lupus, and subacute cutaneous lupus.

Thrombocytopenia is an initial symptom in a small subset of SLE patients (5% to 14%)^{41,42} but has been associated with earlier mortality.⁴³ Therefore, the ability to identify the subset of patients with clinical ITP or TTP who may transition to SLE is clinically important. A number of different studies have evaluated the frequency and associated factors in ITP patients who would transition to SLE. A 1997 study from Mexico of 115 ITP patients requiring splenectomy observed on average for 7.2 years showed that SLE developed in 14 patients (12%).²⁸ Another study from Turkey examined 321 ITP patients, 150 of whom had longitudinal follow-up (average, 2.5 years). Of these 150 individuals, 6 transitioned to SLE.⁴⁴ In pediatric-onset ITP, a 2006 study of 222 children from Israel with 4.2 years' average follow-up found that 3.6% (or 8 of 222) were subsequently classified as having SLE.⁴⁵ Pediatric ITP patients who transitioned to SLE were more likely to have chronic ITP and have higher ANA titers.⁴⁵ Similar findings were demonstrated in a 1997 U.S.-based study of 87 children with ITP in which 9 children transitioned to SLE or a lupuslike disease, all of whom were ANA positive at diagnosis of ITP.²⁹ One pediatric study from Toronto followed the course of 35 children with TTP and found that 9 (26%) met the criteria for

SLE whereas an additional 8 had features consistent with an incomplete lupus phenotype. The best predictor of which TTP patients would transition to SLE was high-grade proteinuria at diagnosis of TTP.⁴⁶

SLE may subsequently develop in a small subset of patients with discoid lupus, and they are usually autoantibody positive at initial evaluation. In a prospective cohort of 150 U.S.-based patients with SLE, 14 originally had discoid lesions and subsequently transitioned to SLE between a few months and 20 years later.⁴¹ Discoid lesions were also found on average years before SLE classification in a Danish cohort (on average 4.5 years before classification¹⁷) and in a U.S. military cohort (on average 3.1 years before classification¹³). Please see Chapter 126 for more information on patients who may transition from one of these other autoimmune rheumatic disorders to the SLE classification.

Transition of patients with only autoantibody production or otherwise dysregulated immune systems to systemic lupus

An earlier preclinical phase of SLE may be when an individual who will subsequently reach the SLE classification has no clinical symptoms but has autoantibodies or other measures of immune dysregulation. Although serologic studies of samples from individuals during this period have demonstrated its existence, longitudinal follow-up of autoantibody-positive, healthy individuals to identify those at highest risk for the development of SLE are not currently available, and this remains an area for future investigation. These studies will be challenging because many healthy individuals may have detectable autoantibodies without clinical symptoms and a systemic autoimmune rheumatic disease will probably not develop in most of them. Please see references 47 to 50 for prevalence and predictors of autoantibody positivity in healthy individuals.

REASONS TO STUDY PRECLINICAL LUPUS AND AREAS FOR FUTURE INVESTIGATION

Several reasons suggest potential benefits in studying preclinical lupus (see Table 125.2 for a partial list). By studying individuals during the preclinical phase, investigators are able to study early disease events without confounding these studies by the influence of immunosuppressive medications, by the sequelae of damage, or by ongoing aggressive inflammation. In addition, by studying patients during these preclinical or early clinical stages, individuals at increased risk for full SLE development or for severe SLE complications may be able to be identified, which could lead to the potential for early intervention before permanent damage occurs. These studies may also result in better understanding of some of the earliest events in lupus

TABLE 125.2
Select reasons for studying preclinical lupus

Reason	Benefit
Understanding disease pathogenesis	Not confounded by disease damage or concurrent medications
Identify at-risk individuals	Allow close monitoring for development of disease and implement early interventions before damage
Prevention studies	Allow development and implementation of prevention studies
Assess disease pathways	Development of disease-specific therapeutic interventions
Identify biomarkers of early disease	Possible development of early screening tests for at-risk individuals; development of improved diagnostics

autoimmunity, which could lead to improved directed diagnostics and identification of biomarkers of early disease activity and potentially provide insight into novel pathways for therapeutic development. In aggregate, multiple studies have demonstrated that selected demographic, clinical, and serologic features can help identify individuals at the highest risk for the subsequent development of SLE.

Early identification will allow closer monitoring and early treatment of major organ involvement. Early intervention would facilitate modulation of the dysregulated immune and inflammatory responses that lead to end-organ damage and the associated increased morbidity and early mortality. Therefore, the field is now poised to be able to use this information to design prospective natural history studies for assessing immune parameters and other serologic responses to identify biomarkers of disease onset and understanding mechanisms of disease to drive directed therapeutic development. Additional cohorts of longitudinal information associated with paired bio-specimens will provide opportunities to ask questions directed at disease pathogenesis and mechanisms of disease, which in turn will provide information on biomarker development, prognostic algorithm development, directed therapeutics, and potential prevention trials.

Acknowledgments

I would like to thank J. Donald Capra, MD, for his critique and input and Julie M. Robertson, PhD, for editing.

Clinical features of systemic lupus erythematosus

■ OLGA DVORKINA ■ ELLEN M. GINZLER

- Systemic lupus erythematosus (SLE) is an inflammatory multisystem disease of unknown etiology with protean clinical and laboratory manifestations and a variable course and prognosis.
- Inflammation in various organs or tissues is due to immunologic aberrations affecting both the innate and adaptive arms of the immune system.
- Serologic abnormalities such as the presence of autoantibodies occur in a predictable course in patients with SLE before the development of clinical features.
- Clinical manifestations may be constitutional or specific, depending on the organ systems involved, including the skin and mucous membranes, joints, kidneys, brain, serous membranes, lungs, heart, and occasionally, the gastrointestinal tract.
- Patients with SLE have various complications caused by the disease or its treatment, in addition to comorbid conditions, such as diabetes mellitus, that may complicate the course of the disease.

INTRODUCTION

Systemic lupus erythematosus (SLE) is an inflammatory, multisystem autoimmune disease of unknown etiology with protean clinical and laboratory manifestations and a variable course and prognosis. Its clinical manifestations may be constitutional or specific, depending on the organ systems involved. The skin and mucous membranes, joints, kidneys, brain, serous membranes, lungs, heart, and occasionally, the gastrointestinal tract may be affected. Inflammation in various organs or tissues is due to immunologic aberrations affecting both the innate and adaptive arms of the immune system.

CLINICAL FEATURES

Serologic abnormalities such as autoantibodies develop in a predictable course in patients with SLE before the development of clinical features.¹ The initial feature leading to the diagnosis of SLE, however, can be variable and ranges from general to organ-specific manifestations, with arthritis being the most common.¹

General manifestations

Constitutional complaints such as malaise, fatigue, fever, anorexia, and weight loss are commonly seen in SLE. These may be the initial features or may be due to complications of the disease.

Fatigue occurs frequently and is a disabling symptom for many patients with SLE. Its strongest correlation is with depressive features, and it is frequently independent of serologic or other clinical manifestations of lupus.²

Fever in SLE is a challenging clinical problem. About 42% of patients with SLE have fever as a manifestation of active lupus. Fever may also result from infections, medications, or malignancies. Lupus is a cause of fever of unknown origin in less than 5% of patients. Although involvement of some organ systems, such as skin disease or arthritis, is common in SLE, any system may be involved in variable combinations with other organ systems. Thus, SLE may have such diverse clinical manifestations as rash and arthritis, pleurisy and proteinuria, or Raynaud phenomenon and seizures or fever

of unknown origin. It is only with a high index of suspicion, a careful history and physical examination, and appropriate laboratory confirmation that the diagnosis can be ascertained.

Cutaneous manifestations

Cutaneous lupus can lead to disfigurement in visible areas such as the face, scalp, neck, and hands and produce major psychological stress, occupational disability, and lower health-related quality of life. A new scoring system—the Cutaneous Lupus Erythematosus Disease Area and Severity Index—was therefore developed to differentiate between disease activity and damage. This activity scale measures erythema, scaling, hypertrophy, and mucous membrane disease, whereas the damage scale measures hyperpigmentation, atrophy, and scarring alopecia.³

The skin lesions seen in patients with lupus can be classified into those that are lupus erythematosus (LE) specific and LE nonspecific. Box 126.1 lists the skin lesions per modified Gilliam classification.⁴

LE-specific lesions can be classified into acute, subacute, and chronic.

Acute lesions may be localized or generalized.⁵ The best recognized localized skin manifestation of SLE is the “butterfly” rash or malar erythema (Fig. 126.1), which is usually manifested acutely as an erythematous, elevated lesion that is pruritic or painful and occurs in a malar distribution. This rash spares the nasolabial folds because of their photoprotected area and fluctuates with disease activity. It may last from days to weeks. Its presence facilitates the diagnosis of SLE, and it is commonly accompanied by other inflammatory manifestations.

Subacute cutaneous lupus erythematosus (SCLE) refers to a distinct cutaneous lesion that is widespread, nonscarring, nonindurated, and photosensitive. This lesion is intermediate between the evanescent malar rash of active lupus and chronic scarring discoid lesions. SCLE lesions commonly occur in sun-exposed areas and may be generalized. They originate as erythematous papules or small plaques with a slight scale and may evolve further into the papulosquamous variant and mimic psoriasis or lichen planus, or they may merge to form polycyclic or annular lesions (Fig. 126.2). SCLE may be accompanied by serologic abnormalities, the most common of which is antibody to Ro (SSA), which has been demonstrated in up to 90% of patients. SCLE lesions are also seen in association with anti-Ro antibodies in other autoimmune disorders such as Sjögren syndrome and rheumatoid arthritis.⁵

Discoid lesions are chronic cutaneous lesions that may occur in the absence of any systemic manifestations—as discoid lupus—or may be a manifestation of SLE. These lesions often begin as erythematous papules or plaques with scaling that may become thick and adherent with a hypopigmented central area. As the lesion progresses, follicular plugging occurs along with the development of scarring with central atrophy (Fig. 126.3). Discoid lesions may occur in the malar region or in other sun-exposed areas. Lesions in the scalp lead to extensive and often permanent alopecia. Discoid lupus may be localized or generalized, the latter being more likely to be associated with systemic features and serologic abnormalities.

Firm, deep subcutaneous nodules may develop as a result of lobular panniculitis and are known as lupus profundus.

Mucocutaneous lesions include ulcers of the mouth, nose (Fig. 126.4), or genital area. Nasal septal erosions occasionally lead to nasal septal perforation.

LE-nonspecific lesions are seen frequently in SLE patients and correlate more with lupus activity. Alopecia is a common feature of SLE. Hair loss may be diffuse or patchy. Alopecia may be due to lupus hairs, which are brittle and break off easily, especially in the temporal and parietal areas of the scalp (Fig. 126.5). Alopecia areata occurs less frequently. It may be associated with exacerbations of the disease, in which case hair tends to

Fig. 126.3 Discoid lupus erythematosus with facial involvement. Note the central scarring with hypopigmentation.

regrow when the disease is under control. Alternatively, it may result from the extensive scarring of discoid lesions, in which case it is irreversible. Alopecia may also be drug induced, for example, from corticosteroids or cytotoxic drugs.

Other nonspecific mucocutaneous lesions seen in individuals with SLE include vesiculobullous and urticarial lesions. Urticarial lesions occur in 5% to 10% of patients, are often chronic, and typically represent cutaneous leukocytoclastic vasculitis, which is frequently associated with hypocomplementemia and characterized by persistent wheals (lasting 48 to 72 hours).

Vasculitic lesions may be manifested as palpable purpura, nail fold or digital ulcerations, subcutaneous nodules, livedo reticularis (Fig. 126.6), splinter hemorrhages, and pulp space and palmar/plantar lesions simulating Osler nodes and Janeway lesions. Digital lesions are usually painful secondary to finger pulp inflammation or ischemic changes and can result in

Fig. 126.4 Mucosal ulcers seen on the hard palate and nasal mucosa.

Fig. 126.5 Alopecia affecting the frontal region of the scalp with lupus hairs.

Fig. 126.6 Livedo reticularis seen over the palmar surface of the hand with digital ulcerations and gangrene.

gangrene⁶ (see Fig. 126.6). Secondary Raynaud phenomenon occurs in more than 50% of patients with SLE and, when severe, can lead to ulcerations, with some progressing to gangrene.

Photosensitivity, reported in more than 50% of patients with SLE, is defined as an abnormal cutaneous reaction to ultraviolet radiation (UVR).⁷ Both LE-specific and LE-nonspecific skin disease may be induced or exacerbated by UVR. In addition to the skin reaction, exacerbations of systemic disease may develop. The mechanism for the photosensitivity is unknown, but it has been suggested that lymphocytes from SLE patients are sensitive to 360- to 400-nm light because of a clastogenic factor in these cells. An increase in apoptotic nuclei was found in the upper epidermal layer of UVR-induced skin lesions. The damaged chromatin may then provide a substrate for autoantibody production, with the subsequent development of a local or systemic inflammatory response. Indeed, studies have shown that ultraviolet B light increases the binding of antibody probes for Ro (SSA) and La (SSB) on keratinocytes in a dose-dependent manner.

Musculoskeletal features

Involvement of the joints as either arthralgia, arthritis, or both is one of the earliest and most common initial manifestations of SLE. Active arthritis, often associated with other features of a new lupus manifestation or active exacerbation, may include swollen inflamed joints with effusions or synovitis (or both) on physical examination.⁸ These symptoms often regress or resolve when other manifestations of active lupus respond to treatment. The deforming arthritis in systemic lupus can be categorized as either a mild deforming polyarthritis, an erosive symmetric polyarthritis with rheumatoid arthritis–like deformities, sometimes referred to as “rhumus,” or a nonerosive Jaccoud arthropathy. Jaccoud arthropathy is a generalized capsular and periarticular condition that affects the hands and results in ulnar drift with subluxation of the metacarpophalangeal joints because of joint instability secondary to lax joint capsules, tendons, and ligaments (Fig. 126.7).

Radiographic findings in patients with Jaccoud arthropathy are usually minimal and consist of subluxations and deformities with no evidence of erosions. In rhupus, the findings are more characteristic of rheumatoid arthritis, with erosions seen in the metacarpophalangeal joints. Magnetic resonance imaging (MRI) identifies edema of the capsule and tenosynovitis in patients with Jaccoud arthropathy, whereas in those with rhupus, MRI shows signs of active synovitis and erosions.

Tenosynovitis is seen in 10% to 13% of SLE patients. Autopsy findings show more marked inflammation in the tendon sheaths than in the synovium. The cellular infiltrate in tendon sheaths is mainly lymphocytes and plasma cells with occasional neutrophils and eosinophils. Marked disruption of collagen fibers within the tendon and sometimes fibrosis or nodules within tendon sheaths have been observed.

Painful, tender rheumatoid nodules histopathologically identical to those present in rheumatoid arthritis have been found in 5% to 7% of SLE patients. They may be an early or a late manifestation and are usually transient and slowly regress with response to therapy. These nodules have been found in the absence of rheumatoid factor and can also be detected in the synovium or tendon sheath.

Patients with SLE may have muscle pain or weakness, or both, secondary to inflammatory myositis, drug-related myopathy, or fibromyalgia. The histologic features of myositis in SLE may not be as striking as in idiopathic polymyositis. Ultrastructural pathology in patients with SLE includes inflammation along with muscle atrophy, microtubular inclusions, a mononuclear cell infiltrate, and fiber necrosis. Traditionally, steroid-induced myopathy is well recognized but may present a diagnostic and therapeutic challenge. With the acceptance of hydroxychloroquine and lipid-lowering statins as common standard-of-care medications for patients with SLE, their association with toxic myopathy must be considered in individuals with muscle complaints.^{9,10}

Fibromyalgia has been identified in 22% of patients with SLE and is somewhat more common than in patients with other arthritides. It is more prevalent in the white population and in patients with concomitant anxiety or affective disorder and to a lesser extent in those with poorer self-reported physical functioning.¹¹ Fibromyalgia has been shown to contribute to reduced quality of life in patients with SLE.

Other rare musculoskeletal features have also been reported in patients with SLE, including relapsing polychondritis and progressive cystic bony lesions. This subset of patients has more central nervous system (CNS) disease, synovitis, and other radiologically observed skeletal abnormalities along with higher concentrations of acute-phase reactants.

In addition to the musculoskeletal manifestations related to autoimmune phenomena, patients with SLE exhibit many complications of previous active disease or its treatment. Distinguishing septic arthritis from active

Fig. 126.7 (a) Patient with Jaccoud arthropathy and swan-neck deformities of the hands. (b) The deformities are reduced when the hands are placed on a flat surface. (From Loma Linda University Medical Center.)

inflammatory arthropathy is one of the most critical diagnostic issues in the management of SLE patients. *Salmonella* infections are more common (seen in 59%) than non-*Salmonella* septic arthritis. These pathogens have been isolated from blood and synovial fluid. Renal disease was the most common SLE-related feature found in patients in whom septic arthritis developed. Patients with multiple comorbid conditions in addition to septic arthritis had higher mortality rates.

Acute joint pain in patients with SLE, especially pain localized to a few areas, most commonly the hips, may indicate the development of osteonecrosis. In most large series, osteonecrosis is recognized as an important cause of disability and occurs in about 10% of patients observed over a long period. No general agreement has been reached on the predictive role of any specific manifestation of SLE, such as Raynaud phenomenon or vasculitis, in the subsequent development of osteonecrosis, and there is currently no general consensus on pathogenesis. Patients in whom osteonecrosis developed had higher Systemic Lupus Erythematosus Disease Activity Index scores in the previous year, probably associated with treatment with higher corticosteroid doses. Findings in a nested case-control study suggested that osteonecrosis is related to previous arthritis, corticosteroid use, and treatment with cytotoxic drugs.¹² Diagnosis of osteonecrosis in patients with focal pain can be difficult. Changes in routine radiographs are late findings (Fig. 126.8). Earlier diagnosis can be made with radionuclide bone scans or MRI to demonstrate bone abnormality.

Spontaneous tendon ruptures are noted infrequently. They can occur at any time during the course of the disease and are not necessarily a late complication. The most common site of tendon rupture is the patellar tendon of the knee, but rupture of the Achilles tendon has also been reported, as well as rupture of non-weight-bearing tendons such as the biceps, triceps, supraspinatus, and extensor tendons of the hands.^{13,14} The most common risk factors are preexisting inflammatory arthritis and tenosynovitis.

Even though gouty arthritis is rare in SLE, gout has developed in patients when their lupus became quiescent. Some of these patients were underexcretors of uric acid, although these studies were done only in patients in whom renal disease developed. Gouty arthritis may be due to hyperuricemia secondary to lupus nephritis, usually with renal insufficiency or end-stage renal disease, and can lead to acute gouty arthritis and tophaceous gout (Fig. 126.9).

Renal manifestations

Renal involvement is one of the more serious manifestations of SLE and is associated with increased morbidity and mortality. Survival has increased from a 4- or 5-year survival rate of 50% in the 1950s to an 80% 15-year survival rate recently, although no change has been seen in the incidence of progression to renal failure.¹⁵

The features most commonly seen in patients with lupus nephritis are proteinuria, urinary casts, hematuria, pyuria, a rising serum creatinine value, and hypertension. Renal biopsy is essential in determining the type of kidney

Fig. 126.8 Advanced avascular necrosis of the hip with collapse of the articular surface and secondary osteoarthritis.

Fig. 126.9 This patient was initially seen with Jaccoud arthropathy, and later during the course of systemic lupus with lupus nephritis, tophaceous gout developed.

TABLE 126.1
Activity and chronicity indices for lupus nephritis

	Activity	Chronicity
Glomerular lesions	Proliferation	Sclerotic glomeruli
	Necrosis/karyorrhexis	Fibrous crescents
	Hyaline thrombi	
	Cellular crescents	
	Leukocytic exudation	
Tubulointerstitial lesions	Mononuclear cell infiltration	Tubular atrophy
	Interstitial fibrosis

Fig. 126.11 Kidney biopsy specimen showing focal proliferative glomerulonephritis (ISN/RPS class III).

involvement because it influences patient management considerably. Most patients with lupus manifest some abnormality on renal biopsy specimens, either on light microscopy or with special techniques such as immunofluorescence or electron microscopy. Apart from glomerulonephritis, renal involvement in lupus can also be due to interstitial nephritis, tubular disease, thrombotic microangiopathy, vasculitis, arteriolosclerosis, and lupus vasculopathy. Biopsy specimens help differentiate between these varied histopathologies and aid in establishing the prognosis. The main indications for biopsy are new-onset or worsening proteinuria, acute renal failure, and failure to respond to treatment or relapse after treatment. Significant renal involvement may be seen even in patients with low-grade proteinuria defined as 1 g/24 hr, thus supporting the role of renal biopsy even in this subgroup. The morphologic features (Table 126.1) seen on kidney biopsy specimens have both prognostic and therapeutic implications.

The earlier World Health Organization classification was revised in 2003 by the International Society of Nephrology/Renal Pathology Society to allow better description and standardization of the lesions (Table 126.2) seen on biopsy.¹⁶ The classification is based on the changes seen on light microscopy, immunofluorescence staining, and electron microscopy. Mesangial lupus nephritis with accumulation of immune complex deposits within the mesangium (class I) progressing to include mesangial hypercellularity (class II) forms the milder spectrum of the renal lesions. Mesangial lupus nephritis (Fig. 126.10) is the most common lesion seen in the subset of patients with clinically silent lupus nephritis. It responds well to renoprotective therapies even without aggressive immunosuppressive regimens. Depending on the percentage of glomeruli harboring subendothelial deposits, lupus nephritis is further classified as focal (Fig. 126.11) (class III;

TABLE 126.2
International Society of Nephrology/Renal Pathology Society (ISN/RPS) 2003 classification of lupus nephritis

Class I	Minimal mesangial lupus nephritis Normal glomeruli by light microscopy but mesangial immune deposits by immunofluorescence
Class II	Mesangial proliferative lupus nephritis Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy along with mesangial immune deposits May be a few isolated subepithelial or subendothelial deposits visible by immunofluorescence or electron microscopy but not by light microscopy
Class III	Focal lupus nephritis* Active or inactive focal, segmental, or global endocapillary or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations
Class III (A)	Active lesions: focal proliferative lupus nephritis
Class III (A/C)	Active and chronic lesions: focal proliferative and sclerosing lupus nephritis
Class III (C)	Chronic inactive lesions with glomerular scars: focal sclerosing lupus nephritis
Class IV	Diffuse lupus nephritis† Active or inactive diffuse, segmental, or global endocapillary or extracapillary glomerulonephritis involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into diffuse segmental (IV-S) lupus nephritis when ≥50% of the involved glomeruli have segmental lesions and as diffuse global (IV-G) lupus nephritis when ≥50% of the involved glomeruli have global lesions. A segmental lesion is defined as a glomerular lesion that involves less than half the glomerular tuft. This class includes cases with diffuse wire loop deposits with little or no glomerular proliferation
Class IV-S (A)	Active lesions: diffuse segmental proliferative lupus nephritis
Class IV-G (A)	Active lesions: diffuse global proliferative lupus nephritis
Class IV-S (A/C)	Active and chronic lesions: diffuse segmental proliferative and sclerosing lupus nephritis
	Active and chronic lesions: diffuse global proliferative and sclerosing lupus nephritis
Class IV-S (C)	Chronic inactive lesions with scars: diffuse segmental sclerosing lupus nephritis
Class IV-G (C)	Chronic inactive lesions with scars: diffuse global sclerosing lupus nephritis
Class V	Membranous lupus nephritis Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations Class V lupus nephritis may occur in combination with class III or IV, in which case both will be diagnosed Class V lupus nephritis with advanced sclerosis
Class VI	Advanced sclerosis lupus nephritis ≥90% of glomeruli globally sclerosed without residual activity

*Indicates the proportion of glomeruli with active and sclerotic lesions.
†Indicates the proportion of glomeruli with fibrinoid necrosis, cellular crescents, or both.
Indicates the grade (mild, moderate, severe) of tubular atrophy, interstitial inflammation, and fibrosis and the severity of arteriolosclerosis or other vascular lesions.
From Weening JJ, D'Agati VD, Schwartz MM, et al, on behalf of the International Society of Nephrology and Renal Pathology Society Working Group on the Classification of Lupus Nephritis. Special feature: the classification of glomerulonephritis in systemic lupus erythematosus revisited. *J Am Soc Nephrol* 2004;15:241-50.

<50% involved) or diffuse (Fig. 126.12) (class IV; ≥50% glomeruli involved). These glomerulonephritides are further described according to the chronicity of the lesions. Membranous lesions (class V) (Fig. 126.13) have mainly subepithelial deposits and may exhibit mesangial involvement. Advanced sclerosis (class VI) is considered the end stage of all the other classes of

Fig. 126.12 Kidney biopsy specimen showing diffuse proliferative glomerulonephritis (ISN/RPS class IV).

Fig. 126.13 Kidney biopsy specimen showing membranous glomerulonephritis (ISN/RPS class V).

lupus nephritis. Lupus vasculopathy may also be seen and is defined by the presence of hyaline thrombi within the arteriolar lumen or intralobular arteries and tubulointerstitial disease with involvement of the tubular basement membrane and atrophy. Some of the other lesions described in lupus are lupoid nephrosis, focal segmental glomerulosclerosis, IgM nephropathy, and amyloidosis.

Renal flares occur in 27% to 66% of patients with lupus nephritis, depending on the study. They carry risk for further renal deterioration and toxicity from additional immunosuppressive therapy. Class IV patients tend to relapse more frequently with nephritic flares, even when they have previously had a complete response. In class V lupus nephritis, anti-C1q antibodies have the best negative predictive value for predicting flares in the absence of antiphospholipid antibodies.¹⁷

Despite advances in the management of patients with lupus nephritis, 10% of SLE patients progress to renal insufficiency and end-stage renal disease.¹⁸ Aggressive treatment of these patients may increase the risk for infection without adding any benefits if no other systemic manifestations of SLE are present. Moreover, these patients have other comorbid conditions that have to be treated aggressively, such as hypertension and dyslipidemia. Some patients maintained on dialysis continue to have clinical or serologic activity. Patients undergoing hemodialysis or peritoneal dialysis may have problems with venous access thrombosis, especially if they have antiphospholipid antibodies.

Most patients with SLE are suitable candidates for renal transplantation. Disease activity after transplantation is not common, probably because of immunosuppression for prevention of transplant rejection. Patients with SLE and antiphospholipid antibodies are at risk for graft thrombosis and loss even in the perioperative period. This subset of patients must be monitored very closely and may need some adjuvant treatment to counteract the procoagulant effect of the antiphospholipid antibodies.

Type 1 and type 4 distal renal tubular acidosis (RTA) have been reported in patients with SLE. There have been case reports of flaccid paresis as the initial feature secondary to hypokalemia from distal RTA.¹⁹ Tubular basement membrane antibody has been reported to lead to interstitial nephritis in patients with SLE, although it is extremely rare. Renal vein and inferior vena cava thrombosis with nephrotic syndrome can occur. Interstitial nephritis (Fig. 126.14) has also been reported in patients with Sjögren syndrome overlapping with SLE.

Inflammatory aseptic cystitis has been described in patients with SLE, and it is diagnostically challenging to distinguishing it from active lupus glomerulonephritis and infection.^{20,21} Reduced bladder volume and a

thickened and irregular bladder wall occur along with symptoms of cystitis. Some patients have ureterohydronephrosis. Immunofluorescence staining of the bladder wall demonstrates immune complex and complement deposition. Both the clinical and radiographic features are generally reversible with corticosteroid therapy.

Neuropsychiatric manifestations

Diagnosis of neuropsychiatric involvement in SLE remains difficult. The American College of Rheumatology (ACR) Ad Hoc Committee on Neuropsychiatric Lupus Nomenclature has proposed a standardized nomenclature for the neuropsychiatric syndromes of SLE.²² The syndromes include 19 different entities (Box 126.2), about 50% of which are directly attributable to SLE, whereas others are found more in association with it. The most frequent manifestations are headache, psychiatric disorders, and cognitive dysfunction, although the only two included in the ACR criteria for SLE are organic brain syndrome and seizures. These syndromes, which do not always correlate with systemic activity, may occur alone or in combination with other neuropsychiatric manifestations.²³

The neurologic finding can be subdivided according to whether the central or peripheral nervous system is involved.

Intractable headaches unresponsive to narcotic analgesics are the most common feature of central neurologic disease in patients with lupus. The headaches may be migrainous or tension type. Active migraine headaches are associated with higher disease activity scores, worsening of Raynaud phenomenon, and the presence of antiphospholipid antibodies. The mean age at onset of these headaches is higher and the subjective response to analgesics is lower in SLE patients than in healthy controls. Headaches may also be secondary to increased intracranial pressure (pseudotumor cerebri) or cerebral vein thrombosis.²⁴

Seizures in SLE patients may be either focal or generalized. Generalized tonic-clonic seizures occur much more frequently than other types of epilepsy. They are associated with active SLE disease, whereas focal seizures may recur at any time irrespective of disease activity. Fifty percent of seizures are due to concomitant infections, metabolic derangements, or iatrogenic complications. The risk for seizures is increased in patients with higher disease activity at baseline, previous neuropsychiatric disease, and anti-Smith and anticardiolipin antibodies.²⁵ The overall prognosis is very good for these patients in the absence of other infectious or comorbid conditions.

Fig. 126.15 (a and b) Cerebral angiogram demonstrating diffuse multifocal anterior cerebral and middle cerebral arteries compatible with vasculitis.

Chorea occurs in less than 2% of patients with neuropsychiatric SLE. It develops early in the course of SLE and resembles Sydenham chorea. An association of chorea with anticardiolipin antibody has been suggested. It usually resolves spontaneously irrespective of therapy. There have also been reports of ataxia with involvement of the cerebellum and basal ganglia in SLE.²⁶

Cerebrovascular accidents (CVAs) can be caused by an occlusive process or embolic episodes. A major intracranial or extracranial occlusive process may be due to thrombosis, dissection, fibromuscular dysplasia, vasculitis (Fig. 126.15), or atherosclerosis. About 90% of CVAs are ischemic and 10% are hemorrhagic.²⁷ The major period of risk for stroke is within the first 5 years after the diagnosis of SLE. Patients with a history of transient ischemic attacks or cardiac valvular lesions are at high (57% and 87%, respectively) risk for stroke. The risk for recurrent CVA is increased in patients who have previously sustained a CVA (64%). Younger SLE patients are at higher risk for CVA than an age-matched population, and this risk decreases with increasing age of the SLE patients.²⁷ Though rare, there have also been reports of intracranial vasculitis²⁸ at times resulting in CVAs. As in individuals without lupus, patients with hemorrhagic CVAs have a higher mortality rate than do those with ischemic strokes.

Neuropathologic findings (Fig. 126.16) attributable to SLE seen in the brain on autopsy include widely scattered, multifocal infarcts characterized by fibrinoid necrosis of small intracortical arterioles and capillaries, petechial hemorrhage, parenchymal necrosis with variable glial reaction, and vascular endothelial cell proliferation. Changes suggestive of healed vasculitic lesions have also been seen in the brain. The strongest correlation of these infarcts has been with the presence of seizures in neuropsychiatric SLE patients.²⁹

Transverse myelitis, though rare, may be a catastrophic manifestation of SLE.³⁰ It can be the initial feature or may develop at varied times during the course of the disease. The level of involvement of the spinal cord varies from small segments to involvement of the entire spinal cord from the medulla oblongata to the conus medullaris. There is a strong association with optic neuritis, as well as with the presence of antiphospholipid antibodies. Even with prompt diagnosis and aggressive treatment, complete recovery occurs in only 50% of patients, partial recovery in 29%, and worsening or no improvement in 21%. Bladder abnormalities tend to persist even after motor recovery. Demyelinating disorders in SLE are also more often reported in association with antiphospholipid antibody syndrome (Fig. 126.17).

Other rare but reported neurologic syndromes in patients with SLE include aseptic meningitis with associated hypocomplementemia and high titers of anti-double-stranded DNA (anti-dsDNA) antibodies, dementia with leukoencephalopathy, and the syndrome of inappropriate secretion of antidiuretic hormone. One of the conditions that is increasingly being reported in SLE patients is a clinicoradiologic entity: reversible posterior leukoencephalopathy syndrome. It is characterized by a rapid onset of headache, seizures, hypertension, blindness, altered mental status, and specific features on MRI. Diffuse hyperintensities on T2-weighted and fluid-attenuated inversion recovery (FLAIR) images in the white matter in posterior areas of the cerebral hemispheres are seen but are completely reversible with blood pressure and seizure control. The overall prognosis is very good, with complete neurologic and radiologic recovery occurring within days.³¹

Cranial and peripheral neuropathies have each been reported in about 10% of SLE patients. The most frequently involved cranial nerves are the

Fig. 126.16 Autopsy findings of fibrin thrombus in a patient with cerebral vasculitis.

sensory and motor nerves of the eye and the trigeminal nerve. Patients may have visual defects, blindness, papilledema, nystagmus or ptosis, tinnitus, hearing loss, vertigo, or facial palsy. Involvement of the postchiasmal visual pathways can also lead to visual hallucinations and cortical blindness. Peripheral neuropathy may include motor, sensory (stocking or glove distribution), or mixed motor and sensory polyneuropathy or mononeuritis multiplex.

An acute ascending motor paralysis indistinguishable from Guillain-Barré syndrome has been described. Myasthenia gravis has also been reported, especially in women younger than 40 years. Autonomic dysfunction is quite common in SLE and does not correlate with disease activity, duration, or damage and organ involvement.³²

The psychiatric manifestations of SLE present a challenge in terms of both diagnosis and management. Organic brain syndrome is defined as a state of diffuse cerebral dysfunction associated with a disturbance in consciousness, cognition, mood, affect, and behavior in the absence of drugs, infection, or a metabolic cause. Frank psychosis has long been recognized as a manifestation of SLE. In about 60% of SLE patients who exhibit psychosis, it can be the initial feature. It tends to occur early in the course of the disease but has a favorable long-term prognosis after intensive immunosuppressive therapy. It is associated with other clinical and biologic features of SLE. Seventy percent of patients have complete resolution of their symptoms, whereas 30% have chronic mild psychotic symptoms.³³ The use of corticosteroids has been implicated in causing psychosis in some patients; however, its relationship to the lupus process can be confirmed by stopping these agents and demonstrating that the psychosis worsens.

Patients with a psychiatric disorder are more likely to have neurologic abnormalities and subjective cognitive impairment than are patients who do not have psychiatric manifestations. Patients with major psychiatric features (e.g., delirium, dementia, organic hallucinations, delusional syndromes, major depressive episodes) have more severe neurocognitive abnormalities, more ophthalmologic abnormalities, and more calcifications on computed tomography (CT) than do patients with mild depressive symptoms or those without psychiatric manifestations.

The prevalence of cognitive impairment in SLE is likely to be underestimated. Hippocampal atrophy in SLE patients is associated with the total

Fig. 126.17 (a) Magnetic resonance image showing abnormal T2 lengthening suggestive of demyelination involving the central midbrain and medulla in a patient with systemic lupus erythematosus and antiphospholipid antibodies. (b) Resolution of the demyelination in the same patient after treatment.

corticosteroid dose, disease duration, and number of CNS manifestations.³⁴ Hypertension, antiphospholipid antibodies, accumulated damage, and lesions seen on MRI are factors that affect the severity of the cognitive dysfunction. Some of the cognitive disturbances can be explained by their coexisting psychiatric disorder. Cognitive dysfunction has also been noted as abnormalities in the areas of attention, memory, and reasoning in patients without other neuropsychiatric manifestations of SLE.³⁵

Interest in assessing neurocognitive function in SLE has increased because patients frequently complain of minor or even significant cognitive abnormalities during both active neuropsychiatric lupus and inactive disease. The ACR proposed a neuropsychological battery for patients with SLE and established the reliability and validity of this ACR SLE battery.³⁶ In a study of neurocognitive function in SLE, more than 80% of SLE patients who had either active or inactive neuropsychiatric involvement and 42% of patients who had never had neuropsychiatric manifestations demonstrated significant cognitive impairment as compared with 17% of patients with rheumatoid arthritis and 14% of normal controls. Regular prednisone use was associated with decreased cognitive functioning in middle-aged patients with SLE.³⁷ Although this effect of prednisone was independent of measures of SLE-associated disease activity, the authors were not able to exclude the possibility that consistent prednisone use was a surrogate for more severe disease.

The diagnosis of neuropsychiatric lupus is primarily clinical. Exclusion of possible causes such as sepsis, uremia, and severe hypertension is mandatory. Evidence of disease activity in other organs is helpful but not always present. Nonspecific cerebrospinal fluid (CSF) abnormalities such as increased cell count, increased protein, or reduced glucose may be present in about one third of patients.

Antibodies to ribosomal P protein are associated with both depression and psychosis. More specifically, anti-N-methyl-D-aspartate (NMDA) receptor antibodies in CSF, especially against the NR2 receptor, are associated with diffuse neuropsychiatric manifestations of SLE. Anti-DNA antibodies cross-react with high affinity with NMDA receptors and can induce neuronal death by apoptosis in animal models.³⁸ In mouse models, high titers of these antibodies in the maternal circulation could lead to histologic changes in the fetal brain during development. This could explain the development of delayed learning in the offspring of mothers with active SLE.³⁹

Electroencephalographic abnormalities are common in patients with neuropsychiatric lupus but are nonspecific.²³ Computerized quantitative electroencephalography may be more sensitive in detecting the subtle electrophysiologic changes associated with lupus. Radionuclide scans have not uniformly been helpful. However, positron emission tomography showing areas of low attenuation that may represent regions of disturbed cerebral circulation and metabolism appears promising.²³ CT findings such as evidence of cerebral infarction and hemorrhage may reflect specific pathologic processes. Cortical atrophy may be found in patients with SLE but does not necessarily reflect CNS disease. Single-photon emission computed tomography (SPECT) has increasingly been used to identify abnormalities

in patients with neuropsychiatric lupus.⁴⁰ Reduced perfusion in watershed areas of the frontal lobes on SPECT correlates with the severity of cognitive dysfunction. A combination of MRI and SPECT may be especially useful in diagnosing neuropsychiatric lupus because the combination of the two is rarely simultaneously normal in patients with neuropsychiatric manifestations.

Gastrointestinal involvement

Any area of the gastrointestinal tract may be involved by SLE or its complications; such involvement may include esophageal disease, mesenteric vasculitis, inflammatory bowel disease, pancreatitis, liver disease, and peritonitis.⁴¹ About 50% of patients may experience anorexia, nausea, and vomiting without clear evidence of involvement of the gastrointestinal tract.

Esophageal symptoms include dysphagia and odynophagia. Dyspepsia and esophageal dysrhythmias are often associated with the Raynaud phenomenon. An association with antibodies to hnRNP1 protein A1 has been noted and may represent a subset that overlaps with scleroderma. Rarely, esophageal perforation has been found in association with vasculitis.

Acute abdominal pain has been reported frequently in lupus patients. When related to active lupus, involvement of the mesenteric vasculature by vasculitis or thrombosis is the most serious gastrointestinal manifestation. Abdominal angina or lower abdominal pain is typical; it may be insidious and occur intermittently over a period of weeks or months. Arteriography may reveal the presence of vasculitis. Bleeding per rectum may occur, and both small bowel and colonic ulcerations may be seen on colonoscopy. Intestinal perforations from mesenteric vasculitis have been described. The most common finding on a CT scan in SLE patients with an acute abdomen is ischemic bowel disease. Emergency laparoscopy may be required to aid in the diagnosis. Thrombosis of mesenteric vessels may develop when associated with antiphospholipid antibodies. This may lead to intestinal infarction, which has high morbidity and mortality rates.

Lupus enteritis may also be manifested as abdominal pain, most commonly affecting the jejunum and ileum. It is characterized by bowel wall thickening, dilated bowel loops, and abnormal bowel wall enhancement (double-halo or target sign) (Fig. 126.18). It is thought to be caused by vasculitis of the bowel wall. Anti-endothelial cell antibody titers are higher in patients with active lupus enteritis.⁴² Biopsy of the bowel wall may show mucosal inflammation and hemorrhage with lymphocytic infiltration of blood vessel walls.⁴³

Involvement of the large bowel may result in symptoms common to inflammatory bowel disease along with biopsy features of ulcerative colitis. It is difficult to establish whether these findings are related to SLE or due to a comorbid condition.

Cases of protein-losing enteropathy have been reported in SLE patients. It is typically manifested as hypoalbuminemia and anasarca in the absence of nephritis. Biopsy of the wall of the small intestine shows C3 deposits within the capillary wall leading to increased capillary permeability.

Fig. 126.18 Computed tomography scan of a patient with lupus enteritis demonstrating bowel wall edema involving the entire small and large intestines, or pancolitis.

Diarrhea is present about 50% of the time. Fat malabsorption has also been reported in up to 10% of SLE patients.

Peritoneal inflammation can give rise to acute abdominal syndrome in SLE patients. Ascites may be associated with peritonitis in about 11% of cases. However, at autopsy, evidence of peritoneal inflammation has been found in up to 60% of cases. When ascites is present in conjunction with abdominal pain and active lupus elsewhere, it generally follows the course and response to treatment of the other features of lupus. However, in a small number of patients, ascites may become chronic. In these circumstances it may be painless and associated with only minimal or no other manifestations of active lupus. The peritoneum may also be thickened with adhesions.

Acute pancreatitis occurs in 5% to 10% of patients with lupus, in 22% of whom it is an initial disease manifestation. It has a 27% higher mortality rate than non-SLE-associated pancreatitis does. Although many medications such as corticosteroids and other immunosuppressive drugs have been implicated in pancreatitis, treatment with these agents generally results in resolution of the pancreatitis and improves the prognosis of SLE patients.⁴⁴

Hepatic involvement is common and most often manifested as increased liver enzymes, including aspartate aminotransferase, alanine aminotransferase, lactate dehydrogenase, and alkaline phosphatase. These abnormalities have been associated with active SLE and the concomitant administration of medications. Disease features include chronic active hepatitis, cirrhosis, granulomatous hepatitis, chronic persistent hepatitis, and steatosis. Hepatic involvement in SLE has been reported, usually in association with antiphospholipid antibodies; it is due to thrombosis of the hepatic artery or veins and results in hepatic infarction, Budd-Chiari syndrome, hepatic venoocclusive disease, nodular regenerative hyperplasia, or only transient elevation of hepatic enzymes.

Rarely, patients with SLE may be seen acutely with symptoms of cholecystitis. Inflammation of the gallbladder with thickening of the wall and fluid around it is noted. Such inflammation can be due to vasculitis or serositis.

Reticuloendothelial involvement

Periarterial fibrosis, or “onionskin lesions,” in the spleen has been considered pathognomonic for SLE. It has been proposed that saturation of the reticuloendothelial system contributes to the prolonged circulation of immune complexes and their subsequent deposition in tissue. Indeed, defective Fc receptor function in patients with SLE has been demonstrated and varies with disease activity. Splenic atrophy has been reported in patients with SLE, and the occurrence of splenic lymphoma has also been recognized.

Lymphadenopathy is a common nonspecific feature of SLE. The nodes are usually soft and nontender and vary in size. In some patients, fluctuation of the lymphadenopathy with disease exacerbations may be noted. Pathologically, the lymph nodes demonstrate reactive hyperplasia. Kikuchi-Fujimoto disease is a histiocytic necrotizing lymphadenitis that is thought to be a self-limited form of SLE. It is a benign condition in which patients have regional cervical lymphadenopathy with tenderness accompanied by fever and night sweats. SLE may eventually develop in these patients, and thus they need to be monitored over the long term.⁴⁵

Hematologic abnormalities

Cytopenias, including anemia, leukopenia or lymphopenia, and thrombocytopenia, are frequent manifestations of SLE, although they may or may not be immune mediated.

Fifty percent of patients with SLE have anemia. The most common causes of anemia in SLE patients are anemia of chronic disease and iron deficiency anemia, followed by autoimmune hemolytic anemia as a distant third.⁴⁶ The Coombs test is positive in only 10% of SLE patients with clinically significant hemolysis. The antierythrocyte antibody in SLE is usually “warm-type” IgG antibody. Other causes of hemolytic anemia, such as medications, infections, and microangiopathic hemolytic anemia, must be ruled out.

Several cases of red blood cell aplasia have been reported. Serum IgG autoantibodies have been detected in patients with red cell aplasia and act to inhibit the growth of burst-forming units of erythrocytes in bone marrow. Pernicious anemia has been described in patients with SLE and anti-intrinsic factor antibodies, low cobalamin levels, and megaloblastic anemia.⁴⁷

White blood cell abnormalities are common in SLE. When leukopenia is secondary to active lupus, the bone marrow is usually normal. The white blood cell count rarely decreases to less than 1500/mm³ in active SLE, unless an additional cause is present. In some instances, when the total white blood cell count does reach such low values, associated high spiking fevers require high doses of corticosteroid to suppress active disease. Neutropenia can be due to autoantibodies that inhibit granulocyte colony-forming units in bone marrow. Neutropenia may also be the result of immunosuppressive agents.

Lymphopenia in patients with SLE is multifactorial and frequently associated with antibodies to lymphocytes. Although it is associated with active SLE, it may also be chronically present in patients with no other clinical disease manifestations. Moderate to marked lymphopenia is generally associated with higher disease activity and damage accrual and is a risk factor for serious infections.⁴⁸

Two distinct subsets of patients with thrombocytopenia have been identified in SLE: a subset in which the thrombocytopenia is one feature of severely active multisystem involvement and a second subset in which the thrombocytopenia is an isolated finding. In the former, the thrombocytopenia tends to require aggressive therapy; in the latter, patients usually have a platelet count lower than 50,000/mm³ without serious bleeding. In both groups, patients may have mild petechiae or purpura. Although antiplatelet antibodies are a frequent finding in SLE, they are not always associated with thrombocytopenia. Other autoantibodies to platelet-specific antigens can also mediate thrombocytopenia, such as antibodies to thrombopoietin receptor and to glycoprotein IIb/IIIa.⁴⁹

In some instances of refractory thrombocytopenia with SLE, often without platelet antibodies, antiphospholipid antibody syndrome should be suspected (see Chapter 139). In addition, thrombocytopenia may be a feature of thrombotic thrombocytopenic purpura (TTP) syndrome, which may complicate SLE.⁵⁰ TTP is characterized by thrombocytopenia, microangiopathic hemolytic anemia, CNS deficits, renal dysfunction, and fevers. In most patients the onset of TTP occurs after the diagnosis of SLE. A high level of suspicion for TTP is appropriate when a patient with SLE exhibits deterioration in multiple organ systems and microangiopathy because aggressive management with plasmapheresis and immunosuppression is indicated.

In addition to a decrease in the number of circulating platelets, defective aggregation in response to collagen also occurs.⁵¹ Various other abnormalities related to platelet function, including acquired von Willebrand factor deficiency, may occur in SLE. Other causes such as infection or drugs must be ruled out as a cause of thrombocytopenia in patients with lupus.

Myelofibrosis has been reported in SLE and may be reversible with immunosuppressive therapy.⁵² In SLE patients with pancytopenia, abnormalities seen on bone marrow biopsy include global hypocellularity, increased reticulin proliferation, plasmacytosis, dyserythropoiesis, myelofibrosis, and necrosis. Pancytopenia in SLE may result from the effects of drugs, particularly immunosuppressive agents. It may also complicate infections in patients with SLE. In addition, pancytopenia may develop in patients with SLE as a result of hemophagocytic syndrome.

Pulmonary involvement

The features of primary pulmonary involvement in SLE include abnormal pulmonary function, lupus pleuritis, acute or chronic lupus pneumonitis, pulmonary hemorrhage, pulmonary embolism, pulmonary hypertension, and airway and diaphragmatic involvement.^{53,54}

The common abnormality in pulmonary function in SLE patients is a restrictive pattern with decreased tidal volume and forced vital capacity. A

Fig. 126.19 Pleural effusion in a patient with systemic lupus erythematosus.

decrease in the diffusing capacity of carbon monoxide is also noted in most SLE patients, especially in those with a previous history of pneumonitis. Causes of the restrictive pattern seen on pulmonary function tests include pleuritis, respiratory muscle involvement secondary to myositis, and phrenic nerve paralysis.

Pleural manifestations have been reported in 30% to 60% of patients with SLE.⁵³ A clinical history of pleuritic pain is more common than radiographic change. Pleural rubs are found less frequently than either clinical pleurisy or radiographic abnormalities. However, autopsy findings of pleural involvement have been detected in up to 93% of patients with SLE.

Pleural effusions (Fig. 126.19) may occur and are generally small but can occasionally be massive. They are also frequently bilateral. When pleural effusions are significant, other causes of effusion such as infection must be ruled out by thoracentesis before treatment is initiated. The fluid is usually an exudate with a higher glucose concentration, lower lactate dehydrogenase levels, and autoantibodies such as antinuclear and anti-dsDNA antibodies. The visceral pleura may contain nodules with immunoglobulin deposits seen on immunofluorescent staining of a biopsy specimen.

Lupus pneumonitis may initially be seen in either an acute or a chronic form. Acute lupus pneumonitis usually occurs during a generalized multi-system lupus flare and is accompanied by fever, dyspnea, coughing, pleuritic chest pain, and occasionally, hemoptysis. Lupus pneumonitis is associated with the presence of anti-SSA antibodies secondary to possible cross-reactivity between SSA and alveolar cell-surface epitopes.⁵⁵ The histopathologic features are nonspecific and consist of alveolar wall damage or necrosis, alveolar edema or hemorrhage, hyaline membranes, and inflammatory cell infiltrates. Electron microscopy and immunofluorescence studies have shown deposition of IgG, C3, and DNA antigen in alveolar septa. Chest radiography and CT show unilateral or bilateral alveolar infiltrates with ground-glass opacification. Patients with acute lupus pneumonitis have been seen with a miliary pattern of nodules on radiographs mimicking pulmonary tuberculosis. Other causes of pneumonitis should be ruled out and empirical antibiotic therapy started because the differential diagnosis includes infections (both bacterial and fungal), as well as hemorrhage and embolism. These patients often require bronchoalveolar lavage as part of their workup and sometimes open lung biopsy to rule out other causes. Though rare, acute lupus pneumonitis simulating lymphangitic pulmonary malignancy has been reported.

Chronic lupus pneumonitis is manifested as interstitial lung disease (Fig. 126.20) and is characterized by dyspnea on exertion, nonproductive cough, fatigue, and basilar rales. The clinical course is associated with late-onset disease, male gender, and older age.⁵⁶ Histopathologic evaluation of the lung is nonspecific, with findings of architectural destruction, interstitial inflammation, fibrosis, and honeycombing alternating with areas of normal lung

Fig. 126.20 Changes of interstitial lung disease showing inflammation.

Fig. 126.21 Diffuse alveolar hemorrhage.

tissue. Gallium scans can be used to help differentiate between active inflammation and fibrosis.

Diffuse alveolar hemorrhage is a very serious condition in SLE, with mortality rates ranging from 50% to 90%.⁵⁷ The characteristic finding is an abrupt onset of dyspnea, cough, fever, and infiltrates and a dramatic fall in hemoglobin. Hemoptysis is present in only 50% of patients. The characteristic histopathology includes diffuse intraalveolar hemorrhage with intact erythrocytes and hemosiderin-laden macrophages (Fig. 126.21). Diffuse alveolar hemorrhage is usually due to a vasculitis with pulmonary capillaritis and a distinctive small-vessel vasculitis or microangiitis of the arterioles and small muscular pulmonary arteries. Evidence of diffuse alveolar damage with diffuse alveolar septal thickening, marked hyperplasia of alveolar pneumocytes, and eosinophilic acellular hyaline membranes may also be noted. Bronchoscopy with bronchoalveolar lavage should be performed to diagnose diffuse alveolar hemorrhage and exclude infection.

Pulmonary hypertension can occur in lupus patients as a result of either the disease process or complications such as pulmonary embolism, valvular heart disease, and interstitial lung disease. It is present in 0.5% to 14% of SLE patients. Survival is significantly lower in SLE patients with pulmonary hypertension than in those with idiopathic pulmonary hypertension.⁵⁸ The initial symptoms are nonspecific and include dyspnea on exertion, fatigue, weakness, and a nonproductive cough, and they often develop insidiously. With progressively increasing pulmonary artery systolic pressure, heart failure ensues. Echocardiography is one of the most important noninvasive screening diagnostic tools for detecting pulmonary hypertension. Suspicion for this disorder should prompt right-sided heart catheterization to determine severity and vasoreactivity, which in turn provides prognostic information. Pulmonary function tests show an isolated reduction in the diffusing capacity of carbon monoxide or a restrictive pattern. Vasoreactive patients have a better prognosis and better response to therapeutic agents than do nonvasoreactive patients.

Pulmonary embolism with or without the presence of antiphospholipid antibodies can develop in SLE patients. In patients with SLE in whom catastrophic antiphospholipid antibody syndrome develops, involvement of the lung is noted in 66% and consists of pulmonary embolism, adult respiratory distress syndrome, pulmonary artery thrombosis, *in situ* microthrombi, or even alveolar hemorrhage.

Shrinking lung syndrome occurs a subset of SLE patients with unexplained dyspnea, small lung volumes with restrictive pulmonary function, and an elevated diaphragm. Chest radiographs may reveal an elevated diaphragm but normal lung fields. The pathogenesis is unclear, but it is probably the result of altered respiratory mechanics because of either impaired respiratory muscle or diaphragmatic function or problems in the respiratory

skeletal apparatus. In a postmortem study the diaphragm of a patient with shrinking lung syndrome in late lupus was fibrotic and thinned.⁵⁹

Airway disease has been reported in patients with SLE. Bronchiectasis and bronchial wall thickening have been detected on high-resolution CT scans of the chest in 35% of patients. Rarely, bronchiolitis obliterans and cryptogenic organizing pneumonia have occurred in association with SLE. Acute reversible hypoxemia and adult respiratory distress syndrome have also been reported in critically ill SLE patients.⁶⁰

Cardiac manifestations

Patients with SLE have a myriad of cardiac manifestations. SLE can affect any layer of the heart and cause endocarditis, myocarditis, and pericarditis, which are generally reflected by symptoms and functional disability.⁶¹

Pericardial effusion secondary to pericarditis is the most commonly observed cardiac feature in SLE. On echocardiography, effusions are seen in more than 30% of SLE patients. Clinically, the findings may be classic for pericarditis, with precordial chest pain and a pericardial rub, or it may be painless and silent. Pericarditis can be fibrinous or fibrous with obliteration of the pericardial space by fibrous adhesions. Pericardial fluid is fibrinous and exudative with chronic inflammatory cells, positive antinuclear and anti-DNA antibodies, and reduced complement activity. Occasionally, incipient or overt cardiac tamponade as a result of pericardial effusions may develop and require high doses of corticosteroids and emergency pericardiocentesis.⁶² Pericardial effusions in SLE patients can also be due to other conditions such as renal failure or bacterial and fungal infections. Rarely, constrictive pericarditis can develop in SLE patients.

Clinical myocarditis is seen in about 10% of SLE patients, but autopsy findings reveal changes secondary to myocarditis in 50% of these patients. Myocarditis should be suspected in patients with arrhythmias or conduction defects, unexplained cardiomegaly with or without congestive heart failure, or unexplained tachycardia. Patients with myocarditis usually have associated pericarditis and other features of active SLE, such as mucosal ulcers. Echocardiography demonstrates global or segmental wall motion abnormalities and a reduced left ventricular ejection fraction. Myocarditis has been associated with anti-SSA or anti-Ro antibodies. Endomyocardial biopsy specimens have shown abnormally thickened small-vessel walls, enlarged smooth muscle cells, and lymphocytic and plasmacytic infiltrates. Mitochondrial clumping, disorganization of myocardial fibrils, moderate interstitial edema, and fibrosis are seen on electron microscopy. Myocarditis is associated with higher disease damage accrual and lower survival in these patients than in those without myocarditis, although 80% of patients improve acutely with immunosuppressive agents and intravenous immune globulin.⁶³

Myocardial involvement in systemic lupus may be subtle, with abnormalities detected only with noninvasive testing. Resting electrocardiograms and echocardiograms are abnormal in more than 70% and cardiac radiographs in 55% of SLE patients. Cardiac MRI in SLE patients with active disease demonstrates an increased T2 relaxation time suggestive of increased tissue edema; this is reversible with improvement of overall disease activity.⁶⁴ Exercise thallium scans in SLE patients have shown segmental perfusion abnormalities in 38%, 50% of which are reversible. Resting dipyridamole technetium 99m sestamibi SPECT shows abnormal myocardial perfusion in 64% of patients. In many of these patients with abnormal noninvasive test results, coronary angiograms have been normal, thus suggesting possible small-vessel disease.

Apart from myocardial involvement, patients with SLE have evidence of cardiac autonomic dysfunction. Sympathetic dysfunction occurs more often in older, postmenopausal patients, as well as in those with hypertension and peripheral neuropathy, whereas parasympathetic dysfunction is seen in older, obese, postmenopausal patients and those who have experienced a CVA.⁶⁵ Periodic heart rate variability is less than would be expected physiologically in SLE patients regardless of treatment. Atrioventricular conduction blocks of various grades have been reported and are associated with anti-Ro antibodies and rarely with anti-U1RNP antibodies. The conduction system is replaced by fibrous tissue similar to that seen with congenital complete heart block secondary to anti-Ro antibodies.

Valvular involvement is common in SLE, with vegetations noted on echocardiography in about 60% of patients. During the course of SLE, these valvular abnormalities may develop for the first time, resolve, persist, or worsen. Diffuse valvular thickening is the most commonly seen abnormality and involves either the mitral or aortic valve. This thickening is associated with reduced mobility of the valve. Verrucous vegetations, known as Libman-Sacks endocarditis, are found in 43% of patients. Vegetations can be present within the left atrium as well and simulate intracardiac tumors. On the aortic valve these vegetations are usually seen on the vessel side.

Fig. 126.22 Coronary vasculitis.

Valvulitis can also involve the tricuspid valves and may progress to either hemodynamically significant stenosis or regurgitation requiring valve replacement. Occasionally, multiple valves are involved in the same patient with Libman-Sacks endocarditis. This endocarditis is associated with antiphospholipid antibodies in about 50% of cases.

Coronary vasculitis (Fig. 126.22) is rare in SLE and can occur with or without other features of active disease. Immunopathologic studies have shown immune complex deposits within blood vessel walls. More frequently, coronary artery disease in lupus is a manifestation of generalized atherosclerosis, which is discussed in greater detail later in the section on complications of lupus. Coronary artery occlusion secondary to intraarterial thrombi may also occur in association with a circulating anticoagulant. Myocardial infarction caused by coronary artery aneurysms have been described as well in SLE. Other vascular involvement, including aortitis, has been seen in patients with SLE. The walls of the aorta exhibit immunoglobulin, complement component, and immune complex deposition.⁶⁶ This inflammation may lead to intraaortic thrombosis or aortic dissection.

Other organ systems involved

Endocrine

Because SLE is known to disproportionately affect women more than men, there has always been an interest in knowing the relationship of sex hormones to the disease. Women with SLE have been shown to have lower androgen levels, with the lowest levels seen in patients with the most active disease.⁶⁷ SLE patients also have increased accumulation of hormones with increased estrogenic activity. Apart from hormonal effects, ovarian vasculitis has been reported with diffuse leukocytic perivascular infiltrates and fibrinoid necrosis in ovarian blood vessels.⁶⁸ The changes of vasculitis have also been reported to involve the adjacent fallopian tube. Male lupus patients have a higher frequency of abnormalities in spermatozoa and testicular Sertoli cell function than otherwise normal men do.⁶⁹

Other endocrine abnormalities may develop in SLE patients during the course of the disease. Hyperprolactinemia has been observed in 20% of both male and female SLE patients and has been associated with antiprolactin antibodies. Prolactin levels, however, do not correlate with disease or serologic activity. Hyperprolactinemic patients may be less responsive to therapy than patients with normal prolactin levels. Prolactin levels have correlated with anti-DNA antibody levels in SLE patients.⁷⁰ The syndrome of inappropriate secretion of antidiuretic hormone has been seen in SLE patients. SLE disease duration has been positively correlated with an inappropriate increase in plasma antidiuretic hormone levels.

Adrenal failure has been associated with antiphospholipid antibodies secondary to hemorrhagic infarction of the adrenal glands or arterial thrombosis of adrenal vessels. Thyroid function test results are frequently abnormal in SLE patients, and hypothyroidism may be more prevalent in this population. Clinical thyroid disease has been found in older SLE patients and is associated with the presence of antithyroid antibodies.

Dyslipoproteinemia along with metabolic syndrome is much more prevalent in SLE patients, but whether it is a result of the disease or its treatment still needs to be elucidated.⁷¹ Autoantibodies against insulin receptors leading to hypoglycemia have also been detected.

Eye, ear, nose, throat

SLE can involve any region of the eye, with keratoconjunctivitis sicca and retinal vascular changes being the most commonly seen. Decreased tear film and reduced tear production occur in about 60% of SLE patients with dry eyes. Retinal vascular changes are due to either immune complex-mediated or microvascular thrombosis. These changes tend to correlate with the

severity of disease. The retinal changes seen most commonly in SLE patients are cotton-wool spots and intraretinal hemorrhages. Other ocular abnormalities include peripheral ulcerative keratitis, choroidopathy, uveal effusions, retinal detachment, optic neuritis, and angle-closure glaucoma. Many of the changes may be a result of the treatments used for SLE, such as corticosteroids for glaucoma, cataract, and central serous retinopathy and anti-malarial agents for maculopathy.⁷²

SLE patients have had sudden-onset sensorineural hearing loss, which may be associated with antiphospholipid antibodies.⁷³ Rarely, laryngeal involvement may be seen as cricoarytenoiditis and as bilateral vocal cord paralysis.⁷⁴

COMPLICATIONS AND COMORBID CONDITIONS

Patients with SLE have various complications resulting from the disease or its treatment. They may also have comorbid conditions that may complicate the course of the disease, such as diabetes mellitus. Other than active lupus during the early years of disease, the main causes of death in patients with SLE are infections and cardiovascular events.⁷⁵

Accelerated atherosclerosis

SLE patients have accelerated atherosclerosis that may be manifested as coronary artery disease, cerebral vascular disease, and peripheral vascular disease. Coronary artery disease is an important cause of morbidity in SLE patients. Studies of the incidence rates of coronary events in women with SLE have shown that patients in the 35- to 44-year-old age group were more than 50 times more likely to have a myocardial infarction than were women of similar age in the Framingham Offspring Study.⁷⁶ SLE patients have an increase in both the traditional and nontraditional risk factors for atherosclerosis. Traditional risk factors such as hypertension, diabetes mellitus, metabolic syndrome, and dyslipidemia are more prevalent in SLE patients, but these risk factors are amplified by the presence of certain nontraditional factors, such as renal failure, higher levels of oxidized low-density lipoprotein, and premature ovarian failure.⁷⁷ Longer disease duration, higher cumulative corticosteroid dose, and older age at diagnosis of SLE are found more frequently in patients who had a cardiovascular event, although the higher corticosteroid doses are thought to reflect the severity of disease. Subclinical atherosclerosis can be determined in SLE patients by using methods such as measurement of carotid intima-media thickness (IMT) and electron B tomography.⁷⁸ SLE patients have increased endothelial dysfunction, vascular stiffness, and carotid IMT when compared with control subjects. Peripheral vascular disease affects about 28% of SLE patients and leads to ischemic extremity ulcers, gangrene, femoral artery plaques, and stenosis.

Malignancies

Patients with SLE have an increased incidence of hematologic malignancies, especially non-Hodgkin lymphoma.^{79,80} The incidence of other malignancies (lung cancer and hepatobiliary cancer) is also higher in SLE patients than in controls.⁸¹

Diabetes mellitus

Diabetes mellitus may be type 1, type 2, or steroid induced in SLE patients. It is present as a comorbidity in SLE patients and can affect the same systems as SLE does. Renal, ocular, and neurologic manifestations can be due to either SLE, diabetes, or both, and this can be a barrier to their management.

These patients may need not only aggressive immunosuppressive therapy for their SLE but also tight glycemic control to prevent complications. It is therefore important to be able to differentiate the cause of the manifestations in patients with both diseases.⁸²

Osteoporosis

Osteopenia is present in 50% of SLE patients and osteoporosis in 17%. Vertebral fractures are detected in at least 26%.⁸³ Fractures are associated with older age, postmenopausal status, increased disease damage, and lower bone mineral density at the hip. Bone mineral density is lower in premenopausal women with SLE, even after adjustment for the corticosteroid dose. However, a prednisone dose equivalent to 7.5 mg/day or greater lowers bone mineral density in the lumbar spine. Exercise is protective at the femoral neck in patients taking corticosteroids. Even in men, lean body mass and bone mineral density are reduced with SLE.⁸⁴

Infections

Infections are the most common cause of morbidity, hospitalization, and mortality in SLE patients.⁸⁵ More than half of the infections are viral, and about 40% are bacterial. The common sites of bacterial infection are similar to those in patients without lupus (i.e., urinary tract, respiratory tract, and skin). The most specific viral infection in SLE is herpes zoster infection. Fungal and protozoal infections are also more frequent in SLE patients.

Hepatitis B infections are found more frequently to coexist with SLE in areas of the world where it is endemic. Reactivation of the virus is a risk, and patients therefore need to undergo serial monitoring of their viral load. SLE patients with chronic hepatitis C infection have an increased frequency of cryoglobulinemia and hypocomplementemia and a lower incidence of cutaneous features and anti-DNA antibodies.⁸⁶ SLE patients with positive HTLV-1 serology have higher lymphocyte counts and require a lower maintenance dose of prednisone for treatment.⁸⁷ Certain infections are becoming more prominent with newer biologic therapies. One example is reactivation of John Cunningham (JC) polyomavirus, which has been reported to lead to progressive multifocal encephalopathy in patients taking rituximab.⁸⁸

The clinical findings in SLE patients with flares and infections are often confusing. It is very important to exclude infections because immunosuppressive treatment of the active flares of SLE can exacerbate infections and even be fatal.

Premature gonadal failure

Accelerated ovarian atresia develops in women with SLE as a result of treatment with chemotherapeutic agents. It is seen more frequently in patients who receive agents such as cyclophosphamide at an older age. Premature gonadal failure also occurs in men with SLE.⁸⁹

CONCLUSION

SLE is a disease that predominantly affects women in minority ethnic groups. As discussed, it can affect any organ or system during the course of the disease. The overall survival rate of patients has considerably improved from 50% at 5 years to higher than 90%. Because of the improved survival, we see more patients in a much younger age group with complications and comorbidities of SLE, such as accelerated atherosclerosis and malignancies. Therefore, in addition to developing newer biologic therapeutic agents for managing SLE, we need to consider developing techniques or discovering biomarkers for prevention or early diagnosis of the complications of SLE.

Genetics of lupus

■ LEAH KOTTYAN ■ JENNIFER A. KELLY ■ JOHN B. HARLEY

- Genetics identifies differences intrinsic to the host that alter the probability of a particular phenotype.
- For lupus, genetics contributes to approximately half the risk for development of the disease, with only about a third of the genetic contribution now identified.
- The known genes implicate pathways that involve particular aspects of the inflammatory response, including pattern recognition receptors and the cascade of signal transduction intermediates, particularly through nuclear factor κ B toward type 1 interferon production. Also, genetic variants in genes influencing immune complex recognition and deposition alter the risk for lupus.
- Much is known but even more remains to be learned about the genetic contributions to lupus.

INTRODUCTION

Systemic lupus erythematosus (SLE) is a complex genetic disorder with no obvious pattern of inheritance conveying risk for SLE in other family members. Indeed, finding a second relative of the first or second degree with lupus occurs in only about 7% of patients with SLE.^{1,2} Still, there is a clear familial tendency, with relatives of SLE patients being at higher risk for disease than other members of the population. Sisters of female lupus patients, for example, are estimated to have an 8- to 29-fold increased risk for the development of SLE.³

These are the usual SLE patients; the exceptional patients who appear to have SLE from a single genetic variant of enormous impact are especially interesting. Although they do not involve genes that ordinarily appear to harbor disease-contributing variants of the more common forms of the disease, they provide much insight into the pathogenesis, as discussed in this chapter.

The genetics of SLE can be considered from many perspectives. There are the traditional allelic, autosomal recessive and dominant, and sex-linked mechanisms. Smaller-magnitude effects from genes that alter risk without a clear understanding of the mechanism constitute the majority of recent genes implicated in the development of SLE.⁴ New mutations, sometimes called *de novo* mutations that first arise in the affected SLE patient and are not found in either parent, probably explain some cases of SLE, including some associated with *TREX1* variants.^{5,6} Lupus is known to be much more common in women than in men, and recent work has suggested that this might be due to the number of X chromosomes, commonly called a gene dose effect (discussed later).^{7,8} To date, no examples of somatic mutations causing lupus in human subjects are available. The technical capacity to evaluate this possibility is now emerging. Indeed, there is no sense of how the many possible environmental factors apparently contributing to SLE might contribute to SLE. Nevertheless, across the phenotype of SLE, many genes operate through a variety of variants and mechanisms, thus providing much complexity to understanding the genetic origins of SLE.

THE BIG PICTURE

Nearly 45 genetic loci containing variants are associated with the development of lupus (probability value, $<5 \times 10^{-8}$) (reviewed in [reference 4](#)) ([Table 127.1](#)), with another 50 or so that also appear close to being established.

Even though many findings suggest that SLE has a strong genetic component, such as the familial aggregation presented earlier^{1,9} and the identical twin concordance rate, which is somewhere between 24% and 50%,¹⁰ the discovery and confirmation of genetic associations have clearly established the importance of genetic variants in the etiology of SLE. Although the probability of the cases and controls having the same allele frequency at any given locus is the major measurement of genetic association, the odds ratio (OR) provides the usual measure of effect size magnitude. Right or wrong, we usually assume that the gene or genes nearest the associated markers are affected by the associated variants. Strikingly, these genes in the neighborhood of the lupus associations are components of specific functions, some overlapping, of the immune response, including immune complex processing, complement activation, receptor activation and immune signal transduction, and interferon activation ([Fig. 127.1](#); also see [Table 127.1](#)). A variant influencing the activity of a gene may operate in one or more cell types at one or more specific stages in development and is engaged in one or more pertinent intracellular relationships, issues that remain largely unexplored. At this point, what is known about expression and cellular function can be used to construct models of cellular responses and interactions that could explain possible mechanisms for how genetic variants alter risk for SLE (see [Fig. 127.1](#)).

GENOMEWIDE ASSOCIATION STUDIES

The major tool for finding disease genes has been the genomewide association study (popularly referred to as a GWAS). Typically in a GWAS, 300,000 to nearly 5 million variable genetic markers are assessed in each case and control. Once thousands of cases and controls are genotyped, the statistical power becomes adequate to detect differences with sufficient confidence (usually set at a probability of chance explaining the finding at 1 in 5×10^8) that the result will usually also be found in a confirmatory study.¹¹ As of this edition, eight GWASs conducted in patients with SLE have reported genetic associations achieving this level of statistical significance.¹²⁻¹⁹

In these GWAS results, most everyone involved is remiss in emphasizing the genes themselves before the particular variations that cause the disease association are known. The associations discovered are with physical pieces of DNA. We assume that the particular association exists because of the function of that piece of DNA, given that chance is the only other known explanatory option. Usually, there are many variants that are possible origins of the disease risk observed because of inexact localization of the origin of the association generated by the disequilibrium that operates throughout the human somatic genome. Identifying the responsible variants and elucidating their mechanism have been the stalling point for progress. Regardless of whether the variants mediate risk through a particular gene, the nearest gene is used as a moniker for the association that happens to be found in their immediate neighborhood.

For each genetic association established by these studies, a small region of genomic DNA associated with SLE is detected by a difference in allele frequency between cases and controls. These markers are not generally the variant that is responsible for the association. Indeed, for the great majority of associations, it is the exception to find a strong candidate variant that has biologic function possibly explaining the association observed, as noted in [Table 127.1](#).

Associated markers typically “tag” a region in the genome that carries with it the causal variant from generation to generation. Consider that there are approximately 37 chromosomal crossovers on the autosomes for each generation.²⁰ These crossover events gradually shuffle genetic variants toward a random distribution across each chromosome, with the process being sufficiently slow that in well-defined ancestral populations, blocks of

*Genetic variants at 45 loci that implicate more than 70 genes as candidates for generating lupus disease risk and participating in the etiology of lupus through association studies, replication in populations of diverse ancestry, and family studies. Variants in *CFHR3/CFHR1*, *NMNAT2*, *ICA1*, *IKKB*, *SCUBE1*, and *CD247* have probabilities approaching genomewide significance ($5 \times 10^{-8} < P < 10^{-7}$) and are the focus of current replication studies. AA, African; AS, Asian; EU, European; HA, Hispanic Amerindian; MAF, minor allele frequency; NF- κ B, nuclear factor κ B; SNP, single nucleotide polymorphism.

LUPUS RISK GENES REGULATE THE IRF5-STAT4-NF κ B CELL SIGNALING PATHWAYS

Fig. 127.1 Lupus risk genes regulate the IRF5–STAT4–NF κ B cell signaling pathways. Engagement of cell surface receptors, either inhibitory or excitatory, induces signaling events involving numerous lupus-associated genes. Proteins shaded in red are coded by lupus risk-associated genetic loci.

DNA appear to be transmitted intact. The average size of these blocks is directly correlated with ancestral age of the population. For European ancestry, which arose from a population bottleneck approximately 50,000 years ago, the inherited blocks have an average size of about 30,000 bases of DNA. African ancestral populations are evolutionarily much older; the last population bottleneck probably occurred 200,000 years ago, thus providing more time and human generations for crossovers to occur and leading to the smaller average inherited blocks observed of about 11,000 bases.²¹ These properties are used in trans-ancestral studies to localize and help identify the causal polymorphisms responsible for the observed genetic associations for phenotypes that occur in all human ancestries, such as lupus. (A caveat: We do not yet have a genetic explanation for why SLE is more prevalent in non-European ancestries.)

In general, the mechanism of how the genetic associations discovered in GWASs are interrelated would be expected to reveal the underlying genetic architecture and specific genetic relationships that lead to pathogenesis. The prejudice, based on decades of experimental data showing specific biologic interactions at the molecular level, was that the genetic interrelationships will be specific and therefore tend to be epistatic, which means that phenotype expression should require multiple simultaneously present variants at different loci. This is not what the results now teach. Instead, they show additive relationships: one genetic association is usually added to the next as though there were no specific interaction between the genetic associations discovered in GWAS projects. How generally true this tentative conclusion really is must await more complete explanations of the origins of genetic risk, but for now we are left with the surprising finding that genetic risk for the usual form of the SLE phenotype is ordinarily additive across disease risk variants.

ISOLATED CASES

Rare cases of a phenotype often provide genetic differences that lead to major insights into pathophysiology. SLE is no exception in this regard.

Early onset with severe disease may mean that a gene with major impact is operating to produce the phenotype. Lupus or lupuslike disease in both humans and mice appears to occur as a single gene defect in more than 35 genes. Two especially informative examples are discussed.

TREX1

Mutations in the 3' exonuclease TREX1 lead to autoimmunity. This is an informative example of how mutations in a single gene can lead to lupuslike disease. The *TREX1* gene is located at chromosome 3p21.31 and encodes a 314–amino acid protein DNA exonuclease that degrades DNA in the cytosol and nucleus, thereby preventing innate immune activation.²² Nuclear DNA left undegraded by dysfunctional TREX1 constitutes a damage-associated molecular pattern (DAMP) and activates pattern recognition receptors leading to the production of type I interferon, which predisposes to the development of lupus autoimmunity. This autoimmunity can be inhibited or ameliorated in murine models by induced genetic dysfunction of *irf3*, *ifn α* , or *rag2*²² or with inhibitors of reverse transcriptase.²³

Autosomal recessive or compound heterozygous variants of TREX1 are found in many children with Aicardi-Goutières syndrome (AGS), in whom lupus often develops. These patients demonstrate neurologic deterioration along with an SLE-like autoimmunity and elevated levels of interferon- α .²⁴ The known TREX1 variants associated with AGS appear to be a mixture of *de novo* mutations and rare polymorphisms.^{5,25} The *de novo* mutations are most often C-terminal frameshift mutations downstream of the catalytic domains. They alter subcellular localization of the TREX1 protein.

Dysfunctional gene products from the *TREX1* gene are also associated with SLE through an autosomal dominant mechanism in cases of familial chilblain lupus.²⁶ Acral dermatoses and cold sensitivity, especially of the hands, and sometimes evidence of systemic autoimmunity develop in infants with this condition.²⁷ The autosomal dominance is thought to occur through the competitive binding of DNA by the catalytically inactive dominant mutants, which precludes access to DNA by active TREX1.^{28,29}

Rare variants of *TREX1* associated with SLE are found in approximately 0.5% to 1% of the usual SLE patients, with a fraction of these variants probably being *de novo* mutations and the others being rare inherited *TREX1* variants.⁵ The development of autoimmunity attributable to mutations in *TREX1* underscores the importance of homeostatic clearance of danger signals from the cytosol, such as undegraded ssDNA, which prevents cell signaling pathways culminating in the production of cytokines such as type I interferons.

Even though *TREX1* is the most common and most studied of the genes and gene products that cause AGS, we would be remiss to omit mention of other genes in this pathway that appear to operate through the mechanism of disrupting the RNase H2 endonuclease complex (*RNASEH2B*, *RNASEH2C*, and *RNASEH2A*) and the deoxynucleoside triphosphate hydrolase *SAMHD1*, which also cause AGS.

Early complement components

The complement system is made up of small soluble proteins found in plasma that act together as a rapid defense against pathogens in the extracellular space and modulate the inflammatory response. Each of the three complement activation pathways (i.e., lectin, classical, and alternative) involves a proteolytic cascade culminating in C3 convertase.³⁰ Once established on the microbial surface, this convertase targets cells both for lysis and for phagocytosis. Meanwhile, the proteolytic by-products of the complement cascade act as small-molecule mediators of inflammation that recruit and activate inflammatory cells, thereby increasing vascular permeability and the expression of cell adhesion molecules. In addition to its roles in the innate immune system, the complement pathway maintains physiologic homeostasis through the clearance of apoptotic cells and immune complexes.³¹⁻³³ Apoptotic cells bind to early complement components, which enhances their capture by phagocytes and hence limits the inflammatory consequences.^{30,33}

Genetic deficiencies of early complement components result in a high likelihood of the development of SLE (reviewed in reference 34). Subjects with deficiencies of the C1 subcomponents (C1q, C1r/C1s) have a very high risk for the development of lupus (>90%), often with severe morbidity and glomerular nephritis.³⁵ Individuals with a deficiency of C4 also have a risk for the development of lupus (≈50%), whereas C2 deficiency results in an incidence of SLE estimated to be between 10% and 20%.^{36,37} When compared with the average lupus patient (a woman with disease onset in her childbearing years and no known predisposition), lupus in patients with deficiencies of C1q, C1r/C1s, or C4 occur with equivalent incidence in females and males and generally have an onset in childhood.³⁸ Notably, no other autoimmune disease, organ-specific disease, or systemic disease exhibits such an association with complement deficiencies.³⁴ These observations underscore the importance of the complement pathway in the pathogenic mechanisms of SLE and the apparent contradiction that on the one hand, complement is consumed by most lupus patients and is used as a measure of disease activity and, on the other hand, its absence increases disease risk. Attenuation of the inflammatory response by complement components, especially by their action in reducing the impact of immune complexes by many mechanisms, appears to explain why their absence is disease inducing.

EXAMPLES OF LUPUS RISK LOCI IDENTIFIED THROUGH POPULATION SAMPLE STUDIES

HLA

The human leukocyte antigen (HLA) region on the short arm of chromosome 6p21 is known to encode more than 180, mostly immunologically relevant genes, including a set of membrane glycoproteins called the major histocompatibility complex (MHC). MHC molecules either present antigenic peptides from the cytosol or internalize extracellular pathogens to T cells. Genes for the MHC modules are among the most polymorphic in the human genome, with a large number of alleles at many of the various HLA loci. Many, if not most autoimmune diseases demonstrate a strong genetic association with variants in this region. Indeed, the first genetic association with SLE was found to involve the HLA region in 1971.³⁹ We still do not know why the histocompatibility antigens are associated with this disorder. It is widely suspected that the HLA relationship underlies a specific critical antigen in the generation of disease, but the identity of this antigen or other reasons for the association remain unknown.

Strong evidence has shown multiple, independent disease associations with SLE in the HLA region; however, the extensive linkage disequilibrium

in this region (>5 megabases) masks the identity of the genes responsible for the observed associations (see reference 40; reviewed in reference 4). Logistically, it is difficult to identify separate, mechanistically independent variants that affect lupus risk because so many of the HLA variants are inherited together. The strongest associations in the region with lupus are at HLA-DRB1 and the class I HLA-B/HLA-C region. Previously reported associations with *TNFB*, *NCR3*, *MICB*, *NOTCH4*, *AIF1*, *BAT2*, *HLA-DQA1*, and *HLADQB1* may or may not be due to their linkage disequilibrium with HLA-DRB1.^{40,41} The specific explanations for why these powerful associations are found with SLE remain unknown.

TNFAIP3

Tumor necrosis factor- α -inducible protein 3 (*TNFAIP3*) encodes the ubiquitin-modifying enzyme A20, which is a critical regulator of inflammation that dampens nuclear factor κ B (NF- κ B) signals through removal of the K63-linked ubiquitin chains and the addition of K48-linked ubiquitin chains from target molecules such as TRAF6. A20 is activated by CD40 and MyD88-linked toll-like receptor (TLR) signaling. When A20 protein expression is reduced, the risk for development of an autoimmune phenotype in murine B cells is increased.

Variants in *TNFAIP3* have reproducibly been associated with the development of lupus (reviewed in reference 4). A recent trans-ancestral study suggested that the causal variant is located in a region of high evolutionary conservation that is normally bound by NF- κ B.⁴² Functional experiments have revealed that a dinucleotide variant attenuates NF- κ B binding affinity and reduces *TNFAIP3* mRNA and A20 protein expression.⁴² Identification of noncoding functional variants that are likely to drive the increased risk for lupus is promising and was made possible by our enhanced understanding of the role of regulatory elements in the regulation of gene expression. Specifically, expansion of known sequences that are bound by transcription factors is making it possible for groups to develop and test hypotheses to explain the molecular mechanisms driving lupus risk associations, such as that seen at the *TNFAIP3* locus.

ITGAM

ITGAM encodes the α -chain subunit of the heterodimeric immune cell integrin CD11b (also called CR3 and Mac-1). It is involved in a variety of adhesive interactions between monocytes, macrophages, and granulocytes and plays a role in the uptake of complement-coated particles. A nonsynonymous variant in exon 3 of *ITGAM* resulting in an arginine-to-histidine conversion at position 77 (R77H) has been reproducibly associated with SLE (reviewed in reference 4). When assessed in a case-only subphenotypic analysis, this variant has most strongly been associated with lupus patients who exhibit renal disease, discoid skin lesions, or immunologic manifestations.⁴³⁻⁴⁵ The R77H variant reduces the affinity of CD11b for intercellular adhesion molecule 1 (ICAM-1) and ICAM-2 and limits the ability of cells expressing the variant to perform iC3b-dependent phagocytosis.^{46,47} A recent trans-ancestral study of the association of multiple members of the integrin-adhesion molecule pathway found that the combined effects of common variation in *ITGAM* and the *ICAM1-ICAM4-ICAM5* locus resulted in an OR of 4.08, one of the highest disease risk genetic associations found in lupus to date.⁴⁸

Many lupus-associated variants are shared with other autoimmune diseases. The *ITGAM* association, however, appears to be somewhat specific to lupus, with conflicting results in studies on systemic sclerosis.⁴⁹⁻⁵¹ Because the risk allele at *ITGAM* reduces the function and binding capacity of CD11b and because this molecule is a receptor for the inactivated fragment of complement component C3 (iC3b), the relevance to lupus may operate through the complement pathway, analogous to the discussion of complement component deficiencies presented earlier.

IRF5-TNPO3

Genetic variants in the interferon regulatory factor 5 (*IRF5*)-transportin 3 (*TNPO3*) region of chromosome 7 have been associated with SLE in every published lupus study and in every ethnicity study testing this genomic region that has been reported to date (reviewed in reference 4). Indeed, of the nearly 50 genetic associations with SLE now identified (see Table 127.1),⁵² the association with *IRF5-TNPO3* ranks first for replication consistency (16 of 16 studies), high for magnitude ($1.4 < \text{OR} < 2.3$), and very low for cumulative probability of an accidental chance association ($P < 1 \times 10^{-50}$). When evaluating SLE subphenotypes, *IRF5* is most closely associated with anti-Ro and anti-dsDNA autoantibodies, where the OR has been found to be as high as 5.83.⁵³

IRF5-TNPO3 has been associated with seven autoimmune disorders (SLE, rheumatoid arthritis, multiple sclerosis, ulcerative colitis, progressive systemic sclerosis, Sjögren syndrome, and primary biliary cirrhosis^{12,54-61}). Furthermore, the efficacy of interferon therapy for multiple sclerosis is associated with *IRF5-TNPO3* variants,⁶¹ and the *IRF5* variants associated with SLE risk have increased efficacy in the treatment of metastatic melanoma after the infusion of extracorporeally interleukin-2 (IL-2)-expanded autologous T cells.⁶²

IRF5 variants are such attractive candidates for disease risk causation because of the extraordinary importance of *IRF5* to the immune response. *IRF5* is a transcription factor important for immune responsiveness, infection, inflammation, and autoimmunity. Indeed, *IRF5* also induces cell cycle arrest and cell death and is required for B-cell differentiation.^{63,64} Within the *IRF5-TNPO3* region, *IRF5* is typically assumed by most investigators to be the primary suspect gene for altering SLE risk, and *TNPO3* is inappropriately ignored. *TNPO3* acts as a nuclear import receptor for serine/arginine-rich proteins such as the splicing factors *SFRS1* and *SFRS2*.⁶⁵ Moreover, *TNPO3* has been shown to be involved in the nuclear transport of human immunodeficiency virus and some other lentiviruses. Perhaps, disease risk directly involves *TNPO3*, or independent genetic effects lead to biologic changes in the activity of both *IRF5* and *TNPO3*. The presently most popular hypothesis among investigators is that functional variants in *IRF5* that decrease expression or activity are responsible for disease risk association.

STAT4 and STAT1

The *STAT4* and *STAT1* genes are neighbors on chromosome 2 and encode proteins that belong to a family of transcription factors originally isolated by their binding to cytokine-inducible genes.⁶⁶ Both *STAT1* and *STAT4* are expressed in hematopoietic cells (including T cells, B cells, and myeloid cells) and the testis.⁶⁷ Importantly, they are both activated in response to IL-12 and type I interferons.^{68,69}

The IL-12 receptor is a heterodimer that consists of IL-12Rβ2 and IL-12Rβ1, which are coupled to the Janus kinases JAK2 and TYK2. After phosphorylation by JAK2 or TYK2, *STAT4* or *STAT1* dimerizes and is translocated to the nucleus, where dimer binding induces gene transcription. This design makes possible a rapid response to cytokine stimuli such that the expressed latent transcription factor is poised until phosphorylated and then quickly initiates the downstream events. In this manner, the levels of *STAT* proteins can rapidly dictate the magnitude of the transcriptional response.

Many groups have confirmed the association of the *STAT4-STAT1* locus in lupus (reviewed in [reference 4](#)). Currently, the genetic association with lupus is confined to 55.5 kb between exons 3 and 5 of *STAT4*, and the genetic association is often referred to as an association with *STAT4*. It remains possible, however, that variants in the associated region have an impact on the expression of *STAT1* or even a distant gene in a way that alters disease risk. The relatively large size of the region of association and the failure to date to reduce the interval supporting the association is the major impediment to progress in identifying the causal polymorphism. Identifying the causal variant driving this association could elucidate how the dysregulation of *STAT4* or *STAT1* (or some other gene) leads to increased risk for lupus.

CD44

The *CD44* gene spans nearly 100 kb and contains 20 exons that encode a cell surface glycoprotein expressed on most immune cells. Expression of *CD44* is complicated by complex splice variations that result in hundreds of protein isoforms (reviewed in⁴). Immunologically, *CD44* plays critical roles in tumor metastasis, hematopoiesis, apoptosis, lymphocyte activation, and immune cell recirculation and homing.⁷⁰⁻⁷² On the cell surface, *CD44* forms heterodimers that bind to a wide variety of ligands that have been directly linked to autoimmunity, including hyaluronic acid, collagens, and matrix metalloproteinases.^{73,74}

Variants of *CD44* were first implicated in SLE as an extension of linkage.⁷⁵ More recently, a large multi-ancestral fine mapping study produced a genome-wide association with variants in a haplotype directly upstream of *CD44* that appear to influence the expression of *CD44*.⁷⁶ The causal variants for the *CD44* association with SLE disease risk remain unknown.

Sex chromosomes

Women are approximately 10 times more frequently affected by SLE than men are. Despite the many family studies and GWAS projects that have been done, the basis of this sex difference in lupus prevalence is not known. Both

the approximately 14-fold higher prevalence of SLE in men with Klinefelter syndrome (47,XXY) and experiments in mice⁷⁷ suggest that this is a gene dose phenomenon, but which gene or genes are responsible have yet to be defined.^{7,8,78} Strikingly, a recent study found that men with lupus have a significantly higher cumulative genetic risk for SLE than women do and a higher level of gene-sex interaction.⁷⁹ Some genetic variants on the X chromosome demonstrate strong statistical association with the development of lupus after adjusting for the mechanism of inheritance of the sex chromosomes.

The genetic associations found in GWASs on the X chromosome would conceivably be candidates to explain the sex difference in prevalence between male and female SLE, but this expectation has not yet been realized.

TLR7

TLR7 binds RNA in endosomes and activates the interferon response through MyD88. A variant of TLR7 has been found in Asian men and women in multiple studies⁸⁰⁻⁸²; however, the extent to which the association with male SLE is of substantially greater magnitude (OR > 4) than the association with female SLE (OR = 1.34) was unanticipated⁸² because this result is counter to what would be expected if this locus contributed to the female predominance in SLE.

Mechanistically, TLR7 is an important pattern recognition receptor of the innate immune system and initiates a signaling cascade that culminates in the production of type I interferons.⁸³ A twofold increase in TLR7 expression was found to be sufficient to lead to autoantibody production and spontaneous autoimmunity in transgenic mouse models.⁸⁴

IRAK1/MECP2

Epigenetic modifications have been shown to affect disease expression in autoimmunity; for example, abnormal T-cell methylation is strongly associated with the pathogenesis of lupus.^{85,86} In T cells taken from patients exhibiting lupus flares, expression of enzymes that maintain DNA methylation during cell division is reduced, and promoters of methylation-sensitive genes are hypomethylated.⁸⁷ Methyl-CpG-binding protein 2 (MECP2) recruits histone deacetylase enzymes to methylated CpG sequences, which leads to compaction of the chromatin and attenuated gene expression.⁸⁸ Furthermore, genetic variants of *MECP2* have been reproducibly associated with the development of lupus (reviewed in [reference 4](#)). *MECP2* and *IRAK1* are neighbors on chromosome Xq28, and both are reasonable candidates to be SLE risk genes. Data supporting an association with *IRFK1* are just as convincing as the association with *MECP2*. Their variants are in high linkage disequilibrium with each other, thus making identification of the causal variant or the critical gene variation challenging. *IRAK1* deficiency abrogates the development of disease in lupus-prone mice.⁸⁹ Further complicating identification of the molecular mechanisms driving the increased risk for lupus in subjects with the risk allele or alleles, *MECP2* regulates the expression of *IRAK1*.⁹⁰ As in many other lupus risk loci, identifying the causal genetic element or elements at this locus may prove to be difficult. We should not eliminate the possibility that variants at both *IRAK1* and *MECP2* contribute to SLE risk.

SOME OPEN QUESTIONS

Each of the genes known to be involved in SLE (see [Table 127.1](#)) has a story analogous to those just presented, which will no doubt mature and provide a much deeper understanding of SLE pathogenesis. We have discussed only a subset of the known genetic associations, now numbering more than 40 and soon expected to number more than 100 genes convincingly associated with SLE. The complexity of SLE pathogenesis is daunting, as has recently been reinforced by the extraordinary data generated from the ENCODE project.

How many gene variants contribute to SLE? Because only a small proportion of the heritability is explained, much is left to learn. Perhaps there will be hundreds of genes. Perhaps better models and more detail will reveal a greater magnitude for the genes that we already know. Perhaps other approaches not yet explored (sequencing, family studies, somatic mutation) will reveal genes and mechanisms that have not yet been amenable to exploration. No doubt all of these possibilities will contribute to a far more complete understanding of lupus genetics.

THE FUTURE OF SYSTEMIC LUPUS ERYTHEMATOSUS GENETICS

Future editions of this textbook are likely to describe the clinically relevant insights from epigenetics and from the recently achieved ability to sequence the human genome. We would expect to find many new genes causing SLE that operate through *de novo* mutation, somatic mutation, recessive, and compound heterozygous mechanisms. These studies are expected to provide a much more complete description of the genetics of SLE, which will aid in

diagnosis, prognosis, and the development of more specific and possibly more effective therapeutics than are now available.

Acknowledgments

An enormous amount of work and resources went into bringing the knowledge of lupus genetics to the point reviewed in this chapter. Unfortunately, because of space restrictions, all of the original sources were unable to be cited individually.

Immunopathology of systemic lupus erythematosus

■ JANE E. SALMON ■ LUMINITA PRICOP ■ VIVETTE D'AGATI

- Systemic lupus erythematosus, the prototypic immune complex disease, is characterized by excessive antibody formation and immune complex deposits in tissue.
- Characteristic lesions include hematoxylin bodies, Libman-Sacks endocarditis, vasculitis, thrombotic microangiopathy, and glomerulonephritis.
- Antibody properties are important in determining the pathogenic potential of immune complexes.
- Complement deficiencies may alter the handling of immune complexes. Genetic variations in receptors for immunoglobulin (Fcγ receptors) influence antibody binding and the pathologic effects of immune complexes.

INTRODUCTION

Systemic lupus erythematosus (SLE), the prototypic immune complex disease, is characterized by excessive autoantibody production, immune complex formation, and immunologically mediated tissue injury. Tissue pathology in all organs reflects a variety of aberrant immunologic mechanisms, but tissue damage in patients with lupus may also reflect nonimmunologic processes. Some aspects of disease, such as early atherosclerosis, may be both initiated and accelerated through immunologic effector mechanisms.

The complexity of the abnormal immunoregulation observed in patients with SLE has made it difficult for clinical investigators to clearly identify the critical elements underlying the immunopathogenesis of SLE. However, several interrelated immunologic elements may be central, beginning with innate immune activation and augmented production of type I interferons. Aberrant adaptive immune responses, related to B-cell and T-cell abnormalities, including defects in B-cell tolerance, autoantigen-specific helper T cells, and intrinsic T-cell functional and biochemical irregularities, result in the production of autoantibodies. Production of at least some of these autoantibodies is driven by increased levels of nucleosomes, perhaps reflecting accelerated apoptosis and defective clearance (waste disposal),¹ and by abnormal cytokine concentrations. The sum of these abnormalities is an array of autoantibodies and circulating immune complexes. Taken together with deficiencies in mononuclear phagocyte function and immune complex clearance, SLE is a critical model for our understanding of immune complex-mediated immunopathogenesis.

Unlike some autoimmune diseases, such as Hashimoto thyroiditis and myasthenia gravis, which are highly organ specific, SLE affects many different organs in a systemic fashion and is not organ specific (Fig. 128.1). In this regard, the autoimmune mechanisms in SLE may be more similar to those found in diseases such as Sjögren syndrome, rheumatoid arthritis, dermatomyositis, and scleroderma, as suggested by Klemperer and coworkers^{1a} in their studies of the “connective tissue” diseases. Certainly, autoantibody formation, immunoglobulin deposition, and primary or secondary infiltration of tissues with mononuclear cells are cardinal features of the disease. Both antigen-specific and antigen-nonspecific immunologic targeting may be important. These processes eventually become apparent through a broad range of pathologic manifestations, including fibrinoid necrosis, hematoxylin bodies, vascular injury, disruption of the dermal-epidermal junction of skin, and glomerulonephritis.

PATHOLOGY

Characteristic lesions

Hematoxylin bodies

Several pathologic findings are characteristic of SLE. Hematoxylin bodies are usually oval or spindle-shaped basophilic structures that may approach the size of an intact cell. Also known as LE bodies, hematoxylin bodies resemble aggregates of chromatin and degenerated cytoplasmic organelles and can be formed *in vitro* from epithelial cell nuclei. Biochemically, they appear to contain both DNA and immunoglobulin,² probably reflecting the interaction of antinuclear antibodies with degenerating nuclear material. Derived from dead cells, hematoxylin bodies are most often described in glomeruli and the endocardium but can occur in almost any organ (Fig. 128.2a). They are identified in only a small number of biopsy specimens but are highly suggestive of SLE. Engulfment of hematoxylin bodies by phagocytes produces the characteristic LE cell, a phagocyte with a large basophilic inclusion (see Fig. 128.2b).

Libman-Sacks endocarditis

At autopsy, the majority of patients who had SLE have nonbacterial, verrucous endocarditis, also known as Libman-Sacks endocarditis. Grossly, these small friable vegetations are often present in large numbers, especially at the forward-flow edges of the valve. The mitral valve is most commonly affected, but verrucae may be seen on other valves, chordae tendineae, and the endocardium. Microscopically, the verrucae consist of proteinaceous deposits and mononuclear cells in the context of platelet thrombi and necrotic cell debris (Fig. 128.3). The occurrence of valvular lesions in association with antiphospholipid antibodies raises interesting speculations about the pathogenesis of verrucous endocarditis, but the valvular abnormalities in primary antiphospholipid syndrome appear to be distinct, with valvular thickening and occasionally nodules but no vegetations.^{3,4} For verrucous endocarditis, it is possible that circulating immune complexes may adhere to the valvular surface, contribute to initial endocardial damage, and serve as a nidus for the deposition of fibrin and platelets.

Cutaneous immunopathology

The pathology of skin lesions illustrates the basic pathophysiologic mechanisms in SLE: immune complex formation with consequent tissue damage, acute vascular and perivascular inflammation, and more chronic mononuclear cell infiltration. Each of these features can be found in the histopathology of cutaneous lupus, although immunoglobulin deposition at the dermal-epidermal junction is the most consistent.

Analysis of lesional skin in SLE may demonstrate liquefactive degeneration of the basal cell layer of the epidermis, fibrinoid necrosis of the dermis, and perivascular and perifollicular infiltrates of inflammatory cells. Chronic lesions exhibit prominent hyperkeratosis and follicular plugging, although these features are less evident in subacute cutaneous lupus and usually absent in acute cutaneous lesions. Disorganization of the basal cell layer of the epidermis is found in chronic cutaneous and subacute cutaneous lesions; it may also be present in acute cutaneous lesions, although it may be more subtle. The mononuclear cell infiltrate, typically with T-cell predominance, in the upper regions of the dermis may disrupt the dermal-epidermal junction in chronic lesions but tends to be more localized to perivascular and periappendageal areas in other lesions.⁵ Edema of the upper dermis with extravasation of erythrocytes can be found in all SLE skin lesions.

In less common forms of lupus skin lesions, the histologic picture is somewhat different. Bullous SLE is characterized by subepidermal bullae without vacuolar degeneration, but with an inflammatory infiltrate (mostly

Fig. 128.1 There are two types of autoimmune disease: organ specific and systemic. Although the systemic autoimmune diseases produce symptoms in several organs, each disease may be marked by characteristic patterns of organ involvement. CNS, central nervous system.

Fig. 128.2 Hematoxylin bodies. (a) A glomerulus containing several lilac hematoxylin bodies, which correspond to exposed nuclei in which the chromatin has undergone swelling and clumpy transformation after complexing with ambient antinuclear antibody (hematoxylin-eosin). (b) LE cells. Two phagocytic cells have ingested large basophilic inclusions. The inclusions, termed *hematoxylin bodies* when seen before ingestion, contain DNA and IgG (Wright stain). (With permission from Professor I.M. Roitt.)

neutrophils) in the dermal papillae.⁶ In lupus profundus or lupus erythematosus panniculitis, deep dermal and subcutaneous involvement with nodules is seen. Lesions in the epidermis may or may not accompany nodule formation.⁷

In almost all cases, deposits of immunoglobulin (IgG, IgA, and IgM) and complement components from the classical and alternative pathways are observed along the dermal-epidermal junction at the site of cutaneous lesions. In the majority of patients with systemic disease, immunofluorescence reveals similar deposits at the dermal-epidermal junction in normal non-sun-exposed skin and at sites of cutaneous lesions. This characteristic immunofluorescence, the lupus band test (Fig. 128.4), may be helpful in diagnosis, although it can also be positive in patients with rheumatoid arthritis, Sjögren syndrome, dermatomyositis, progressive systemic sclerosis, and other clinical conditions.⁷

The dermal-epidermal localization of immunoglobulin and complement may result from accumulation in the subepidermal space of nuclear material derived from apoptotic keratinocytes. At the highly vascular dermal-epidermal junction, these nuclear antigens may have the opportunity to react with circulating autoantibodies, to form antigen-antibody complexes and precipitate as immune aggregates, and to initiate tissue injury. This model suggests a basis for the photosensitivity in SLE whereby ultraviolet irradiation leads to increased apoptosis of keratinocytes, increased nuclear

Fig. 128.3 Libman-Sacks endocarditis. Two verrucae on the surface of this valve contain fibrin and necrotic cell debris. Inflammatory cells are localized primarily at the endocardial surface (hematoxylin-eosin).

Fig. 128.4 Cutaneous immunopathology and the lupus band test demonstrating immunoglobulin and complement deposition in non-sun-exposed skin. (a) Light microscopy reveals thickening of the dermal-epidermal junction and inflammatory cells associated with a dermal appendage (hematoxylin-eosin). (b) At a higher power, immunofluorescence demonstrates IgM and C3b at the dermal-epidermal junction (bright green horizontal band seen midway through this section). (With permission from Brostoff J, Scadding GK, Male DK, Roitt IM. *Clinical immunology*. London: Gower; 1991.)

debris, and subsequent precipitation of immune complex material at the dermal-epidermal junction. Though attractive, this model does not fully reconcile the presence of immunoglobulin at the dermal-epidermal junction with the absence of accompanying tissue damage and the presence of a lymphocytic infiltrate suggestive of cell-mediated immunity.

Vascular immunopathology

Several types of vascular lesions may occur in SLE. The most common lesion is immune complex deposition in the walls of small arteries and arterioles (Fig. 128.5).⁸ In some instances, the vascular immune deposits occur without an associated inflammatory response and can be demonstrated only by immunofluorescence and electron microscopy. In others, the vascular immune deposits are accompanied by perivascular infiltrates of mononuclear leukocytes. Necrotizing large- or small-vessel vasculitis with fibrinoid necrosis and neutrophil infiltration resembling that seen in polyarteritis nodosa, microscopic polyangiitis, or antineutrophil cytoplasmic antibody (ANCA)-associated granulomatous vasculitis is relatively uncommon (Fig. 128.6). The necrotizing vasculitis occurring in SLE can be distinguished from that of microscopic polyangiitis or ANCA-associated granulomatous vasculitis by the presence of immune deposits in the vascular wall and the absence of ANCAs. Presumably, these pathologic and serologic distinctions reflect different pathophysiologic mechanisms.

Fig. 128.5 Vascular immune deposits in systemic lupus. Immune complex deposition is demonstrated in the wall of a small intrarenal artery with antibody to human IgG (immunofluorescence, anti-IgG).

Fig. 128.6 Necrotizing small-vessel vasculitis in systemic lupus. The vasculitis resembles the lesions seen in polyarteritis nodosa/microscopic polyangiitis. Transmural infiltration by lymphocytes and neutrophils can be seen, along with endothelial degeneration and intimal fibrinoid necrosis (hematoxylin-eosin).

The vascular lesions of thrombotic microangiopathy may occur in patients with lupus who have circulating anticardiolipin antibodies, lupus anticoagulant, or both and less commonly in those in whom hemolytic-uremic syndrome develops in association with autoantibody to the von Willebrand factor–cleaving protease.⁹ The lesions of thrombotic microangiopathy in SLE are morphologically indistinguishable from those occurring in hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura. They are characterized by intraluminal fibrin thrombi that may be acute or organizing, but without any accompanying vascular immune deposits (Fig. 128.7).

Immunopathology of lymphoid organs

Lymphadenopathy, either regional or generalized, is a common manifestation of SLE that affects up to 60% of patients.¹⁰ More frequently identified in children and Black individuals, lymphadenopathy may be the initial clinical manifestation of SLE.¹¹ The enlarged cervical, axillary, and inguinal lymph nodes measure up to several centimeters and are typically discrete, soft, and nontender. Histologically, follicular hyperplasia, sometimes forming giant or coalescent follicles, is noted along with enlarged germinal centers and increased numbers of plasma cells and immunoblasts in the interfollicular zones.¹² Hyperplasia and focal necrosis of the paracortical T-cell zones are also observed. Necrotic foci containing hematoxylin bodies are a particularly characteristic, but rare finding. The demonstration of immunoglobulin and complement C3 in the necrotic walls of arterioles and venules suggests immune complex–mediated vasculitis in the pathogenesis of the necrosis. A predominance of paracortical CD11b+CD15+ histiocytes and CD8+ T cells is found adjacent to the necrotic zones.¹³ Lupus-related lymphadenopathy must be distinguished from the tender lymphadenopathy arising from secondary infections or the emergence of a lymphoproliferative disorder after chronic immunosuppression.

Splenomegaly occurs in 10% to 45% of patients, depending on the mode of detection. There is poor correlation between the occurrence of splenomegaly and coexistent cytopenia. The follicular hyperplasia is typically accompanied by periarterial fibrosis of the penicilliary arteries, which produces a distinctive onionskin lesion with multiple tight concentric rings of perivascular collagen. Adjacent calcified fibrous nodules may be observed.¹⁴ Onionskin lesions (Fig. 128.8) have been described in the majority of spleens at autopsy but are not pathognomonic for SLE. Their morphogenesis is unknown, although a role for healed arteritis has been proposed.

Fig. 128.7 Vascular lesions of thrombotic microangiopathy in systemic lupus. (a) Acute thrombotic lesions with occlusion of the arteriolar lumen by fibrin thrombus that stains eosinophilic (left panel). This intraluminal fibrin produces an orange-staining reaction with the Lendrum stain for fibrin (right panel). The endothelium appears necrotic and desquamated; however, no leukocyte infiltration of the vessel wall is evident. (b) An organized thrombus with recanalization severely narrows a small artery in the kidney from a patient with lupus anticoagulant (hematoxylin-eosin).

Hyposplenism, infarction, and rupture of the spleen have been reported rarely in association with vasculitis of splenic arteries or thromboses related to circulating lupus anticoagulant.

Renal immunopathology

The renal manifestations of SLE, collectively termed *lupus nephritis*, are extremely heterogeneous.¹⁵ All four renal compartments—the glomeruli, tubules, interstitium, and blood vessels—may be affected. The incidence of clinical renal disease underestimates the prevalence of pathologic renal involvement, especially if routine light microscopy is supplemented by the more sensitive techniques of immunofluorescence and electron microscopy. The morphologic features of lupus nephritis are also extremely protean, with the capacity to transform, either spontaneously or in response to treatment.

Lupus nephritis is one of the few renal diseases in which immune deposits can be detected in any or all renal compartments, including the glomeruli, tubules, interstitium, and blood vessels. IgG is found almost universally (>98%) and is usually dominant in intensity. Co-deposits of IgM and IgA are common. Deposits of complement C1 and C3 and properdin can be demonstrated in the majority of cases, consistent with activation of both the classical and alternative complement pathways. When deposits of all three immunoglobulin classes and both C1 and C3 are found, the designation “full house” staining is often applied.

Approach to classification

Investigators have attempted to define and quantify the many morphologic lesions of lupus nephritis in a comprehensive, systematic fashion.¹⁶ Widespread use of the World Health Organization (WHO) classification has improved the uniformity and reproducibility of interpreting biopsy

specimens and has provided the standardized nomenclature essential for clinicopathologic studies addressing outcome and prognosis.¹⁷ In 2004 based on recommendations by the International Society of Nephrology and Renal Pathology Society, the WHO classification underwent minor revision to provide sharper distinctions between the classes (Table 128.1).¹⁸

Even though tubular, interstitial, and vascular lesions are common in lupus nephritis and may contribute significantly to overall disease severity, activity, and chronicity, the WHO classification is based entirely on evaluation of the glomerular alterations. Accurate classification requires careful assessment of the glomerular alterations by light microscopy, followed by integration of the immunofluorescence and electron microscopic findings. The first step is to determine whether glomerular hypercellularity is present in the mesangial, endocapillary, or extracapillary zones. The distribution of the endocapillary hypercellularity is assessed (focal: <50% of the glomeruli affected; diffuse: ≥50%). Attention is given to the presence of infiltrating leukocytes, necrotizing lesions, and glomerular basement membrane thickening. These light microscopic findings are then interpreted in the context of the distribution of the glomerular immune deposits in mesangial, subendothelial, and subepithelial locations as detected by light microscopy, immunofluorescence, and electron microscopy.

The overall distribution of immune deposits detected by immunofluorescence can be refined further at the ultrastructural level. Mesangial electron-dense deposits are typically observed in all classes of lupus nephritis. Mesangial deposits are the defining feature of class I and II and can be considered the common substratum on which the higher classes are built. Both class III and class IV lupus nephritis display subendothelial and mesangial deposits. The distribution of the subendothelial deposits is more focal and segmental in class III and more diffuse and global in class IV, which corresponds to the general distribution of the endocapillary proliferative lesions. Although scattered subepithelial deposits may also be detected in class III and class IV, regular subepithelial deposits are a distinguishing feature of class V.

Class I and class II designate glomerular disease limited to the mesangium (Fig. 128.9). In class I, the glomerular mesangium is normocellular;

Fig. 128.8 “Onionskin” lesion. Concentric periarterial fibrosis in the malpighian body of the spleen leads to this characteristic structure (hematoxylin-eosin). TABLE 128.1
World Health Organization classification of lupus nephritis (2004)

Class	Description
I	Minimal mesangial lupus nephritis
II	Mesangial proliferative lupus nephritis
III	Focal lupus nephritis
IV	Diffuse segmental (IV-S) or global (IV-G) lupus nephritis
V	Membranous lupus nephritis
VI	Advanced sclerosing lupus nephritis

Fig. 128.9 Lupus nephritis class II (mesangial proliferative lupus nephritis). (a) Mild mesangial hypercellularity without compromise of the glomerular capillary lumina (hematoxylin-eosin). (b) Granular deposits of IgG are confined to the mesangial stalk, with sparing of the peripheral glomerular capillary walls (immunofluorescence, anti-IgG). (c) Electron micrograph showing four individual glomerular capillaries oriented around a central mesangial stalk. Electron-dense deposits are present within the central mesangial region (arrow) but do not extend into the peripheral glomerular basement membranes.

however, immune deposits confined to the mesangium can be detected by fluorescence microscopy and electron microscopy. In class II, these purely mesangial immune deposits are accompanied by mesangial proliferation (defined as three or more mesangial cells in mesangial areas away from the vascular pole, as assessed in histologic sections 3 μ m thick).

Most investigators consider class III and class IV lupus nephritis to be qualitatively similar glomerular lesions that differ only in severity and distribution. The glomerular endocapillary lesions are classified according to whether they are focal (affecting <50% of the glomeruli) or diffuse (affecting $\geq$ 50% of the glomeruli) or are segmental (affecting less than half of the glomerular tuft) or global (affecting half or more of the tuft). In assessing the number of glomeruli affected, both active (proliferative) and chronic (sclerosing or scarred) lesions must be taken into account. Class III lupus nephritis consists of a focal, predominantly segmental, endocapillary proliferative glomerulonephritis that affects less than 50% of the glomeruli (Fig. 128.10). Class IV (diffuse) lupus nephritis is distinguished from class III arbitrarily on the basis of involvement of more than 50% of the glomeruli by endocapillary lesions. Typically, the endocapillary proliferation in class IV is relatively diffuse and global (designated IV-G) (Fig. 128.11).¹⁸ However, some cases of class IV lupus nephritis may exhibit a diffuse segmental distribution (designated IV-S).¹⁸ Glomerular endothelial cells, monocytes, lymphocytes, and neutrophils may contribute to the endocapillary hypercellularity (Fig. 128.12a). As in class III, lobules without endocapillary proliferation usually manifest varying degrees of mesangial proliferation (see Fig. 128.10b).

Common light microscopic features of active class III and class IV lupus nephritis include wire loop (subendothelial) deposits, hyaline thrombi, necrosis, hematoxylin bodies, and cellular crescents. Subendothelial immune deposits are the *sine qua non* of active class III and IV lupus nephritis and are typically detectable by immunofluorescence and electron microscopy in

the distribution of the endocapillary proliferation. When large enough to be detected by light microscopy, subendothelial deposits may form “wire loop” thickenings of the glomerular capillary walls (see Fig. 128.12b to d). Some cases of class III or class IV lupus nephritis manifest large intracapillary deposits forming “hyaline thrombi” (see Fig. 128.12b). This term is a misnomer inasmuch as they do not represent true fibrin thrombi but are massive intracapillary immune aggregates. Glomerular necrosis consists of a focus of smudgy fibrinoid degeneration of the glomerular tuft (see Fig. 128.10b). Necrosis may be accompanied by any or all of the following: deposition of intracapillary fibrin, glomerular basement membrane rupture, and apoptosis of infiltrating neutrophils producing pyknotic or karyorrhectic nuclear debris (“nuclear dust”). Although they are the only truly pathognomonic lesions of lupus nephritis, hematoxylin bodies are extremely uncommon and are found in less than 2% of biopsy specimens of lupus nephritis. These smudgy, lilac-staining structures are the tissue equivalent of the LE body and consist of naked nuclei in which the chromatin has been altered by binding to ambient antinuclear antibodies (see Fig. 128.2a). Cellular crescents are a feature of active lupus nephritis that may be encountered frequently in both class III and class IV disease. They are common overlying necrotizing lesions but may also occur in glomeruli with nonnecrotizing endocapillary proliferative lesions.

Active glomerular lesions that persist over time or do not respond to treatment may lead to glomerular scarring (or sclerosis), a feature of chronic and irreversible glomerular injury. In class III, the glomerular scarring is typically focal and segmental, mirroring the distribution of the proliferative and necrotizing lesions. Associated fibrous crescents may form synechiae to the sclerotic segments. Similarly, in chronic class IV lupus nephritis, the glomerular sclerosis is typically more global and diffuse. Of course, glomerular obsolescence is not restricted to class III and class IV but can also supervene on class V. Glomerular sclerosis in lupus nephritis may also occur

Fig. 128.10 Lupus nephritis class III (focal lupus nephritis). (a) Low-power view showing three glomeruli with segmental endocapillary proliferation causing obliteration of the glomerular capillary lumina in a portion of the glomerular tuft. Adjacent glomerular capillaries are patent. The endocapillary proliferation affected less than 50% of the total glomeruli sampled in this biopsy specimen, consistent with focal lupus nephritis (Jones methenamine silver). (b) Individual glomerulus with segmental occlusion of the glomerular capillaries by endocapillary proliferation with infiltrating leukocytes and fibrinoid necrosis. The remainder of the glomerular tuft displays mesangial hypercellularity (hematoxylin-eosin). (c) Deposits of IgG are identified in the peripheral glomerular capillaries of a segment of the tuft (corresponding to an area of endocapillary proliferation). Mesangial deposits are present in the adjacent glomerular lobules (immunofluorescence, anti-IgG).

Fig. 128.11 Lupus nephritis class IV (diffuse lupus nephritis). (a) Low-power view showing the diffuse and global distribution of endocapillary proliferation, consistent with class IV-G (hematoxylin-eosin). (b) Diffuse and global deposition of IgG throughout the glomerular mesangium and outlining the peripheral capillary walls (immunofluorescence, anti-IgG).

Fig. 128.12 Lupus nephritis class IV (diffuse lupus nephritis). (a) The glomerular capillary lumina contain many infiltrating leukocytes, including neutrophils. Some of these neutrophils are undergoing apoptosis and forming pyknotic or karyorrhectic nuclear debris (hematoxylin-eosin [H&E]). (b) Several glomerular capillary walls are thickened by eosinophilic deposits that form thick “wire loops.” Some of the immune deposits are so large that they obliterate the glomerular capillary lumina and form “hyaline thrombi” (H&E). (c) By immunofluorescence, the wire loop deposits correspond to large peripheral capillary wall immune deposits located in the subendothelial region. These deposits are comma shaped because they conform to the smooth outer glomerular basement contour (immunofluorescence, anti-IgG). (d) Seen on electron microscopy, the wire loop consists of a large circumferential subendothelial electron-dense deposit that forms along the inner aspect of the glomerular capillary wall between the glomerular endothelium and the glomerular basement membrane.

in the course of aging or as a complication of hypertensive arterionephrosclerosis and does not necessarily imply scarring in the course of immunologically mediated injury.

Membranous lupus nephritis (class V) is characterized by diffuse thickening of the glomerular capillary walls as a result of numerous subepithelial electron-dense deposits often separated by basement membrane spikes (Fig. 128.13). This lesion usually occurs on a background of mesangial hypercellularity and mesangial immune deposits. Because scattered subepithelial deposits may also be encountered in class III and class IV lupus nephritis, the designation membranous lupus nephritis should be reserved for cases in which subepithelial deposits predominate. In a case of class III or IV lupus nephritis, an additional diagnosis of class V is warranted if subepithelial deposits are present in 50% or more of glomerular capillaries or 50% or more of the glomeruli.

The modified WHO classification recognizes a sixth class in which the findings are those of extremely chronic, advanced glomerulonephritis and widespread glomerular scarring.¹⁷ In 2004 this class was defined more specifically as global sclerosis affecting at least 90% of glomeruli without residual activity. Most examples of class VI lupus nephritis undoubtedly represent advanced class IV disease. In some cases the process is so “end stage” that a diagnosis of chronic lupus nephritis is difficult to make on morphologic grounds. Immunofluorescence and electron microscopy may reveal residual small granular electron-dense deposits in the thickened glomerular capillary walls, tubulointerstitial compartment, or vessel walls.

Tubulointerstitial lesions can be encountered in all classes of lupus nephritis, particularly class IV, and correlate closely with the degree of functional renal impairment. Active lesions include interstitial inflammation by lymphocytes, monocytes, and plasma cells, in addition to immune deposits in tubular basement membranes, interstitial collagen, and the walls of interstitial capillaries (Fig. 128.14). The poor correlation between the severity of interstitial inflammation and the presence or amount of tubulointerstitial immune deposits implies a more complex role for cell-mediated immunity.¹⁹ Analysis of T-cell receptor clonotypes has revealed an oligoclonal interstitial T-cell population that persists in repeated biopsy samples, a finding that supports participation in adaptive immunity.²⁰

Prognostic features

Prognosis correlates with the class of lupus nephritis and with measures of activity and chronicity. The prognosis is excellent in class I and II, more guarded in class III and V, and poorest in class IV (particularly in patients with high chronicity and persistent activity that is resistant to treatment). Attempts to quantify the degree of activity and chronicity in lupus nephritis are predicated on the intuitive assumption that active lesions are more amenable to treatment and chronic lesions represent largely irreversible damage. Assessment of disease activity and chronicity provides a helpful, albeit inexact guide to prognosis and treatment. Activity indices, first formulated in the 1960s, have been refined and popularized by Austin's group as the National Institutes of Health (NIH) Activity and Chronicity Index. According to the NIH schema, the activity index is calculated by summing the score for each of six histologic features (glomerular endocapillary proliferation, glomerular leukocyte infiltration, glomerular subendothelial hyaline deposits, glomerular fibrinoid necrosis or karyorrhexis, cellular crescents, and interstitial inflammation), which are graded individually on a scale of 0 to 3+ (0, absent; 1+, <25% of the glomeruli affected; 2+, 25% to 50% of the glomeruli affected; 3+, >50% of the glomeruli affected). The scores for glomerular necrosis and cellular crescents are accorded double weight because of their more ominous importance. Interstitial inflammation is graded as 1+ (mild), 2+ (moderate), or 3+ (severe). The sum of these values gives a total possible activity score of 0 to 24. Similarly, chronicity is graded on a scale of 0 to 12 by summing each of the following four features of chronicity (each scored as 0 to 3+): glomerular sclerosis, fibrous crescents, tubular atrophy, and interstitial fibrosis.

The NIH group initially found an activity index greater than 12 and a chronicity greater than 4 to be predictors of a poor outcome. In subsequent analyses, the combination of cellular crescents and moderate to severe interstitial fibrosis was a sensitive predictor of doubling of the serum creatinine concentration.²¹ The value and reproducibility of these indices have been debated. Schwartz and coworkers noted problems in intraobserver and interobserver reproducibility.²² Although there does not appear to be a precise cutoff for activity and chronicity that predicts outcome, it is generally agreed that greater chronicity portends a worse prognosis. Despite their

Fig. 128.13 Lupus nephritis class V (membranous lupus nephritis). (a) The glomerular capillary walls are diffusely thickened and have a rigid appearance. Associated mild mesangial hypercellularity is apparent but without evidence of endocapillary proliferation (hematoxylin-eosin). (b) A silver stain delineates the characteristic "spikes" that project at right angles from the glomerular basement membranes, like bristles on a comb (Jones methenamine silver). (c) The immunofluorescence pattern is finely granular and corresponds to deposits along the outer aspect of the glomerular capillary walls (immunofluorescence, anti-IgG). (d) Electron micrograph showing subepithelial electron-dense deposits (arrows) located on the outer aspect of the glomerular capillary wall between the visceral epithelial cells (podocytes) and the glomerular basement membrane. Some of these deposits are separated by intervening projections of glomerular basement membrane material, which results in the appearance of "spikes" (arrowhead). Deposits are also seen in the adjacent mesangial matrix deep to the glomerular capillary lumen.

Fig. 128.14 Tubulointerstitial lesions in active lupus nephritis. (a) The renal interstitium is expanded by edema and dense inflammatory infiltrates (hematoxylin-eosin). (b) Example with extensive immune deposits in the interstitial connective tissue and outlining the tubular basement membranes (immunofluorescence, anti-IgG). (c) Immunostaining for CD68 shows many monocytes/macrophages within the renal interstitium between tubules (immunocytochemistry, anti-CD68).

limitations, activity and chronicity indices are of particular value when repeated biopsies are performed in individual patients to monitor disease evolution and response to treatment.

The 2004 classification has provided a framework to test the distinction between classes IV-S and IV-G. Class IV-G disease typically has greater proteinuria, renal insufficiency, and hypocomplementemia, more subendothelial deposits, and less fibrinoid necrosis than class IV-S disease.²³ Some cases of class IV-S disease have a paucity of subendothelial deposits and are associated with ANCA seropositivity, thus suggesting a different pathogenesis.²⁴ Most studies have found that class IV-G disease has a similar renal outcome as class IV-S disease.^{25,26}

Pathogenetic mechanisms

The morphologic subtypes of lupus nephritis are defined according to the distribution of immune deposits within the glomerular tuft. However, we know surprisingly little about the factors that govern the localization of immune deposits within the glomerular filter. It is likely that the diverse morphologic expressions of lupus nephritis reflect differences in the composition and properties of immune complexes, including immune complex load, specificity, size, avidity, affinity, charge, and immunoglobulin isotype (see later). It has been proposed that a mesangial pattern of immune

deposition is favored by a relatively small immune complex load of intermediate-sized, high-avidity complexes that resist elimination by mesangial clearing mechanisms. Larger quantities of intermediate-sized or large immune complexes could overwhelm the mesangium and spill out into the subendothelial zones. Some experimental evidence supports the formation of subepithelial deposits from smaller, low-avidity, cationic immune complexes in relative antigen excess, which may dissociate and reform *in situ*, perhaps favored by electrostatic interactions with the polyanionic constituents of the glomerular capillary wall.

In the past, the paradigm for lupus nephritis has been a classic type III hypersensitivity reaction mechanism of glomerular deposition of circulating autoantibody-containing immune complexes, followed by complement activation and subsequent neutrophil-mediated tissue injury. In recent years, emphasis has shifted away from the exclusive role of renal deposition of preformed circulating immune complexes to recognize the importance of local formation of immune deposits.^{15,27,28} Charge interactions favor the local binding of positively charged nucleosomes to fixed anionic sites in the glomerular capillary wall. Once planted in the glomerular filter, these autoantigens may interact with circulating autoantibody and thereby lead to *in situ* formation of immune complexes. Some anti-DNA antibodies exhibit a range of cross-reactivities to normal glomerular constituents, such as

Fig. 128.15 Endothelial tubuloreticular inclusion. On an electron micrograph a large endothelial tubuloreticular inclusion is identified within a glomerular endothelial cell. This intracytoplasmic inclusion consists of interanastomosing tubular structures located within the dilated endoplasmic reticulum of the endothelial cell cytoplasm (arrow).

heparan sulfate proteoglycans, laminin, and type IV collagen, which suggests another potential mechanism of *in situ* immune complex formation.²⁹ Finally, the poor correlation between the quantity of circulating immune complexes and the activity of the glomerulonephritis implies a potential role for local antigen presentation at the level of the glomerulus by activated macrophages or T cells. Fc γ receptor (Fc γ R)-bearing monocytes appear to be essential effector cells in glomerulonephritis, as demonstrated by protection of Fc γ -deficient mice from the development of nephritis but not from the glomerular deposition of immune complexes or complement.³⁰

Neutrophil and monocyte recruitment is particularly marked in active lupus nephritis. A complex network of cytokine activation appears to mediate their influx and promote downstream effects on mesangial proliferation, matrix production, and crescent formation.¹⁵ Inflammatory and fibrogenic cytokines that have been demonstrated to be upregulated in lupus nephritis include monocyte chemoattractant protein type 1 (MCP-1), interleukin-1 (IL-1), IL-2 receptor, IL-6, interferon- γ (IFN- γ), IFN- α , tumor necrosis factor- α (TNF- α), and transforming growth factor- β (TGF- β). The morphologic correlate of increased interferon concentrations is the presence of tubuloreticular inclusions (“interferon footprints”) in the endothelial cell cytoplasm of all classes of lupus nephritis (Fig. 128.15).

A newly recognized entity in SLE is lupus podocytopathy, which is manifested as nephrotic syndrome and diffuse podocyte foot process effacement in the absence of significant immune deposits in the glomerular capillary wall.³¹ The biopsy findings resemble those of minimal change disease or focal segmental glomerulosclerosis and are highly responsive to corticosteroids, thus suggesting possible T-cell-mediated cytokine effects directed at glomerular podocytes.

Central nervous system immunopathology

Involvement of the central nervous system (CNS) in SLE is common and can assume diverse clinical and morphologic manifestations. Neurologic involvement directly attributable to the immunopathologic derangements of SLE must be distinguished from the effects of drugs (e.g., corticosteroids), hypertension, and infections that complicate immunosuppressive therapy. Although the term “lupus cerebritis” is used in common medical parlance to describe the pathologic manifestations of SLE in the brain, most cerebral involvement is actually attributable to vascular lesions.³² In the past, the majority of vascular pathology in the CNS was believed to represent lupus vasculitis, a vascular inflammation caused by deposition of immunoglobulin and complement in vessel walls, as may occur in other organs. It is now recognized that although such necrotizing or inflammatory vasculitis does account for less than 15% of the vascular lesions of CNS lupus, more than 70% of the vascular pathology is attributable to thrombotic lesions of small intracranial vessels, with or without associated endothelial proliferation and perivascular inflammation.³³ Most patients with thrombotic vasculopathy have associated anticardiolipin or antiphospholipid antibodies and lack

immune complex deposition in the vessel walls. There are also rare reports of arterial thromboemboli that have been linked to Libman-Sacks endocarditis.

The parenchymal injury that occurs secondary to lupus vascular lesions (whether inflammatory, thrombotic, or thromboembolic) usually takes the form of microinfarcts or macroinfarcts, sometimes complicated by hemorrhage in subarachnoid, subdural, or intracerebral locations.³⁴ Hemorrhage may also result from bleeding tendencies caused by thrombocytopenia or hypoprothrombinemia in the context of anticardiolipin/antiphospholipid antibody syndrome, immune thrombocytopenic purpura, or thrombotic thrombocytopenic purpura. Depending on the location of the vascular lesions and the distribution and extent of the parenchymal injury, the clinical findings vary widely from localized neurologic deficits (e.g., paresis, cranial nerve palsy, movement disorder, and seizure) to more generalized manifestations (e.g., headache, altered consciousness, psychosis, and impaired cognition). Interestingly, deposition of immune complexes may occur in the choroid plexus, a specialized vascular structure with filtration functions that bears some similarities to the renal glomerulus.

CNS disease of nonvascular origin appears to be less common and less well understood. In most cases no identifiable pathologic lesions are found. A potential role for antineuronal and antigial antibodies has been proposed. Some of these antibodies have specificity for neurofilaments or brain synaptic plasma membrane antigen and can be demonstrated with complement-dependent cytotoxicity assays on cultured human neuronal cell lines. A subset of antilymphocyte antibodies have also been shown to cross-react with neurons. Recent evidence suggests that antibodies to the glutamate receptor may contribute to neurocognitive dysfunction. Anti-DNA antibodies capable of cross-reacting with neuronal excitatory N-methyl-D-aspartate receptors have been detected in the sera and spinal fluid of SLE patients and mediate neuronal apoptosis.³⁵ An association has also been found between anti-ribosomal P protein and the development of lupus psychosis, although the underlying pathophysiology and anatomic correlates remain to be defined.

Cardiac immunopathology

Pathologic changes can occur in the endocardium, myocardium, and pleuropericardial membranes.^{36–39} The occurrence of nonbacterial verrucous endocarditis, characteristic of SLE, also suggests a role for autoantibodies and perhaps immune complexes. Pericarditis is commonly seen in postmortem series, regardless of whether patients had symptomatic evidence of pericarditis. Gross morphologic evaluation reveals a fibrinous exudate, whereas microscopic examination shows perivascular mononuclear cell infiltration with edema and fibrinoid necrosis. A granular pattern of immunofluorescence for IgG is consistent with immune complex deposition.

Clinically significant inflammatory myocardial disease is uncommon, but atherosclerotic coronary artery disease is increasingly being recognized.^{40–42} The role of vasculitis as an initiating event and the roles of continuing vasculitis, corticosteroids, and hypertension as accelerating factors are unclear.^{38,39} Deposition of immune complexes may promote the accumulation of cholesterol in atherosclerotic plaque. Myocardial infarction may also occur as a result of intracoronary thrombotic events without significant atherosclerotic disease.⁴³ Clinical studies support the concept that chronic inflammation drives the development of atherosclerosis in patients with and without SLE. The precise contribution of infiltrating leukocyte subpopulations, autoantibodies, oxidized lipoproteins, and cytokines in the pathology of atherosclerosis in lupus is an area of intense investigation.⁴⁴

Pulmonary immunopathology

Acute lupus pneumonitis occurs in less than 10% of lupus patients. It is characterized by acute alveolar wall injury, including alveolar edema and hemorrhage, hyaline membrane formation, interstitial pneumonitis, and alveolitis.⁴⁵ Vasculitis and hematoxylin bodies are rarely identified. Demonstration of immunoglobulins and complement and ultrastructural identification of electron-dense deposits in the alveolar walls and arterioles support a role for pulmonary immune complex deposition. Acute lupus pneumonitis appears to be more common in patients with anti-Ro antibodies.⁴⁶ Chronic diffuse interstitial lung disease eventually develops in up to 50% of patients with acute lupus pneumonitis. Chronic lupus pneumonitis is distinguished by interstitial fibrosis and chronic interstitial lymphoid infiltrates, septal thickening, and hyperplasia of type II pneumocytes. Pulmonary hypertension has been associated with the development of plexiform microvascular lesions, as well as with medial hypertrophy and intimal fibrosis of branches of the pulmonary artery. A role for anti-endothelial cell antibodies has been proposed.⁴⁷ In addition, deposits of IgG with anti-DNA activity, as well as

IgM and C3, have been demonstrated in the walls of pulmonary blood vessels.⁴⁸ In shrinking lung syndrome, breathlessness without cyanosis is accompanied by reduced chest expansion and atelectasis. Weakness of the respiratory muscles, including the diaphragm and intercostal muscles, may cause a chronic restrictive defect on the basis of fibrosing lupus myopathy.⁴⁹ In many cases, pleuritic inflammation promotes reflex inhibition of diaphragmatic activity.⁵⁰

PROPERTIES OF IMMUNE COMPLEXES

Although not all manifestations of SLE can be attributed to immune complexes, these complexes do appear to play a central role in the pathogenesis and immunopathology of SLE. Thus, critical questions in pathogenesis focus on the nature of the immune complexes and their handling, the nature of the autoantibodies that make up the complexes, and the basis for the increased production of these autoantibodies.

Antibodies and antigens

Of the five classes of human immunoglobulins (IgG, IgM, IgA, IgE, and IgD), IgG is the most common constituent of the immune complexes found in SLE. IgM is more typically associated with lower-affinity antibodies, and IgA often reflects stimulation of mucosal immunity. IgG has four subclasses, each of which has distinct physicochemical and immunologic properties (Table 128.2) that reflect differences both in primary amino acid sequence

and in glycosylation of the subclass-specific heavy chains (Fig. 128.16).⁵¹ The genes encoding immunoglobulin heavy chains are located on the long arm of human chromosome 14.

IgG1 is the most common immunoglobulin in serum, and both IgG1 and IgG3 are produced primarily against protein antigens. IgG2, the second most common immunoglobulin, is typically produced in response to polysaccharide antigens. IgG4 production is associated with prolonged antigenic stimulation. In addition to the nature of the antigen, regulation of IgG subclass production is influenced by the antigen-presenting cells and cytokines released at the time of antigen presentation. There is no doubt that the nature of the IgG subclass in an immune complex influences both the biologic properties of the immune complex *in vivo* (Table 128.3) and the ability to detect the immune complex *in vitro*.

One of the most striking differences among the IgG subclasses is found in the structure of the hinge region (see Fig. 128.16). The lower hinge region participates in binding of the early complement component C1q to IgG and in binding of IgG to its corresponding cell receptors (FcγRs).⁵² Binding of IgG to different FcγRs is sensitive to specific residues within this region in the second constant domain of the heavy chain (C_H2). It is likely that C1q and FcγRs interact with composite sites on IgG, that is, a tertiary structure

TABLE 128.2
Properties of human IgG subclasses

	IgG1	IgG2	IgG3	IgG4
Serum levels (% of total)	60-65	20-25	5-10	3-6

consisting of several different linear regions, conformational determinants, or both. Glycosylation of IgG also influences binding to FcγR; IgG acquires antiinflammatory properties on Fc sialylation with preferential binding to inhibitory FcγR. Variations in the composition of sugar moieties thereby dramatically change antibody-mediated activity.⁵³

Antigens are also critical constituents of immune complexes, not only because they influence the nature of the humoral immune response but also because their own physicochemical properties strongly influence the nature of the complex (see Table 128.3). In addition to size and valence (see the next section), the antigen may also have unique properties that influence its handling. Nucleosomes, which may bind both C-reactive protein and specific antibody as opsonins, may also bind directly to the negatively charged basement membrane of the glomerulus. In SLE, increased apoptosis or impaired clearance of apoptotic blebs (or both) may trigger the release of immunogenic chromatin material. In addition, persistent neutrophil extracellular traps (NETs) released by dying neutrophils during NETosis may serve as a source of modified chromatin⁵⁴ that allows formation of immune complexes with antichromatin antibodies.

Critical properties of immune complexes

The formation and the fate of soluble immune complexes depend on the biophysical and immunologic properties of the antigen and the antibody (see Table 128.3). Such properties include the size, net charge, and valence of the antigen; the class and subclass of the antibody; the affinity of the antibody-antigen interaction; the net charge and concentration of antibody; the molar ratio of available antigen and antibody; and the ability of the immune complex to interact with proteins of the complement system.⁵⁵ Complement fixation is more efficient with larger complexes. Larger complexes also present a broader multivalent array of ligands for complement and FcγRs to bind. Finally, of course, the class and subclass of antibody are important in complement activation and determining which FcγRs can be engaged.

In the clinical setting it is difficult to evaluate these variables, but experimental models have provided ample evidence that they are very important. Large complexes are cleared more rapidly than small ones, complexes between antibody and double-stranded DNA bind to a receptor for a complement fragment (C3b) on erythrocytes (complement receptor type 1 [CR1]) differently than do certain antibody-protein complexes, and complexes with a net positive charge localize to the glomerulus more efficiently than do those with a neutral charge.

Pathogenic mechanisms

Once deposition of an immune complex in tissue has occurred, either through *in situ* formation or by direct immune complex deposition, FcγR-mediated uptake by antigen-presenting cells can lead to amplification of the humoral immune response, and FcγR-mediated activation of mast cells and phagocytes, in addition to activation of complement, leads to an inflammatory response through the generation of soluble mediators, including complement fragments C3a and C5a. These mediators attract and activate polymorphonuclear leukocytes and mononuclear phagocytes; cause the release of additional inflammatory mediators from these cells, mast cells, and basophils; and activate large granular lymphocytes (Fig. 128.17). Binding of immune complexes containing ribonuclear proteins to FcγRs on plasmacytoid dendritic cells can also trigger the secretion of IFN-α and perpetuate the autoimmune responses.⁵⁶ Activation of platelets may cause platelet aggregation and microthrombi, in addition to release of vasoactive compounds that increase vascular permeability. The production of reactive oxygen metabolites, release of hydrolytic enzymes, and secretion of cytokines can cause direct destruction of local tissue and further stimulation of leukocytes. Thus, the continued presence of immune complexes in chronic immune complex-mediated diseases can lead to prolonged tissue damage, which may result in clinically evident vasculitis, pleuropericarditis, cutaneous lesions, and glomerulonephritis.

BIOLOGY OF IMMUNE COMPLEX HANDLING

Normally, antigen-antibody immune complexes are removed quickly and safely by the *mononuclear phagocyte system*, a collective term for the fixed tissue phagocytes found primarily in the liver and spleen. However, when both the antigen and antibody are present for prolonged periods and when defects in the immune complex clearance mechanisms are present, immune complexes may be deposited in host tissues, with subsequent tissue damage. SLE is characterized by defective handling of apoptotic debris leading to the

Fig. 128.17 Immune complex activation of inflammation. Immune complexes activate complement, with release of C3a and C5a. In turn, C3a and C5a stimulate neutrophils, mononuclear phagocytes, basophils, and mast cells and induce the release of inflammatory mediators. Immune complexes deposited on the vessel wall cause further deposition of complement and lead to both Fcγ receptor-mediated and complement-mediated stimulation of phagocytic cells.

Fig. 128.18 Immune complex clearance in systemic lupus erythematosus. Clearance of antibody-opsonized erythrocytes (EA) is dramatically decreased in patients with active systemic lupus erythematosus (SLE). The EA probe is a sensitive measure of mononuclear phagocyte system Fcγ receptor function. In contrast to the initial clearance of EA, clearance of soluble immune complexes (IC) is more rapid in patients with SLE. Some data indicate that this more rapid disappearance from the circulation does not correspond to an increase in the uptake of immune complexes by the mononuclear phagocyte system but rather reflects greater deposition of immune complexes in the capillary beds as a result of deficiencies in the complement system (see text). However, at later times (15 minutes), clearance of soluble immune complexes is delayed, which may reflect the same Fcγ receptor dysfunction observed with the EA probe.

formation of immune complexes.^{1,57} *In vivo* and *in vitro* abnormalities in both FcγR- and complement-mediated clearance of immune complexes have been described in SLE.⁵⁸⁻⁶⁰ For example, patients with SLE display delayed clearance kinetics of certain IgG-coated erythrocytes, a model immune complex that is used to assess FcγR-mediated clearance (Fig. 128.18). Interestingly, some soluble immune complexes disappear from the circulation of patients with SLE more rapidly than from the circulation of normal

individuals, but this difference may reflect rapid deposition in peripheral tissues as a result of inefficient complement-mediated immune complex solubilization rather than enhanced complement-mediated removal by the mononuclear phagocyte system. Abnormal receptor-mediated clearance contributes to immune complex deposition and is correlated with disease activity (Fig. 128.19), but other factors, such as size and composition, preexisting tissue inflammation, and opportunity for charge-charge

interactions, also influence immune complex handling. The vascular endothelium and the glomerular basement membrane are highly susceptible tissue targets for immune complex damage.

Role of complement in immune complex handling

To prevent disease mediated by immune complex deposition, a number of protective mechanisms have evolved that effectively eliminate immune complexes both from the circulation and from tissues. Central to these protective mechanisms is the complement system, the same system implicated in the pathogenic destruction of tissue.⁵⁷ In addition, C-reactive protein, which can mediate complement fixation, also has an important role, especially in the handling of nuclear debris. Several fundamental points about the complement system deserve emphasis here. Immune complex handling (and clearance) is strongly influenced by three roles of the complement system:

- Complement C1q binds to the immune complexes, and receptors for C1q are important in the uptake of these complexes.
- Complement activation maintains the solubility of immune complexes by preventing the formation of large insoluble immune aggregates and by transforming insoluble complexes into smaller soluble ones.
- Complement activation leads to the opsonization of complexes with complement components or fragments for recognition by complement receptors on phagocytes.

Receptors for both C1q and C3 degradation products (C3b, iC3b, and C3dg) are important in immune complex binding, internalization, and subsequent release of inflammatory mediators.

Receptors for the Fc region of IgG
Structure and function

Immune complexes containing IgG antibodies engage receptors for the Fc region of IgG (FcγRs). In contrast to the complement receptors, which bind fragments of complement components, FcγRs bind IgG ligand in its native form and require clustering or cross-linking of at least two receptors on the same cell to initiate intracellular signaling.⁶¹⁻⁶³ Presumably, this requirement for clustering prevents circulating IgG or complement components from stimulating effector cells in the absence of antigen. Cross-linking of FcγR triggers internalization by FcγR-expressing cells and leads to degranulation by phagocytes and mast cells, immediate release of inflammatory mediators, and synthesis and release of cytokines.^{61,63}

The three families of FcγRs—FcγRI, FcγRII, and FcγRIII (Table 128.4; Fig. 128.20)—are encoded by distinct genes on the long arm of human chromosome 1q21-23. Each family member has distinct ligand-binding properties and is differentially expressed on various cell types (Tables 128.5 and 128.6).^{61,63,64} FcγRI and FcγRIIIa also bind C-reactive protein and serve as its receptors in humans. As members of the immunoglobulin supergene family, all share the common structural motif of two or three immunoglobulin-like disulfide-linked domains in the extracellular portion of the receptor (see Fig. 128.20). Although these receptors share similar but not identical extracellular domains, the transmembrane and cytoplasmic tails are highly divergent. Differences in the promoter regions of FcγR genes lead to differences in their regulation and expression. This extensive diversity is responsible for the variety of functions that these receptors can elicit (see Fig. 128.20 and Table 128.5).^{61,63}

Fig. 128.19 Clinical activity was assessed in terms of both renal and nonrenal manifestations. Longer (taller) clearance half-time values represent greater degrees of dysfunction. Patients with active renal and nonrenal disease showed the greatest degree of Fc receptor-mediated impairment of clearance. (Modified from Kimberly RP, Salmon JE, Edberg JC, et al. The role of Fcγ receptors in mononuclear phagocyte system function. Clin Exp Rheumatol 1989;75:103-8.)

TABLE 128.4
Human Fcγ receptor families

Membrane anchor	TM γ chain	TM	TM	a1: TM a2: secreted	TM	TM	γ/ζ Complex*	GPI

By convention, distinct genes within an FcγR family are designated with an uppercase letter, whereas the protein products from these genes are designated with the corresponding lowercase letter.
*γ/ζ Complex: although FcγRIIIa is a transmembrane protein, a member of this family of signal-transducing molecules is required for cell-surface expression of FcγRIIIa.
GPI, glycosylphosphatidylinositol membrane anchor; TM, conventional transmembrane protein.

Fig. 128.20 All Fcγ receptors (FcγRs) have extracellular domains composed of two (or three for FcγRIa) disulfide-bonded immunoglobulin superfamily motifs. FcγRIa and FcγRIIIa share the same γ chain. The signaling motif used by FcγRIIb is an immunoreceptor tyrosine inhibitory motif (ITIM), which is similar to the immunoreceptor tyrosine activation motif (ITAM) but has only one tyrosine that forms a docking site for molecules that include an src-homology domain type 2-containing tyrosine phosphatase. The signaling motifs engaged by FcγRIIIb are not completely understood.

TABLE 128.5
Fcγ receptor cellular distribution

Gene family	Isoform	Cell types
FcγRI	a	Monocytes, Mfs, IFN-γ- or G-CSF-stimulated PMNs, IFN-γ-stimulated eosinophils, DCs
	b/c	mRNA encoding FcγRIb is present in monocytes, Mfs, IFN-γ-stimulated PMNs
FcγRII	a	Platelets, PMNs, monocytes, Mfs, Langerhans cells, DCs, mast cells (B cells, NK cells)
	b	B cells, monocytes, Mfs, DCs, PMNs
	c	mRNA present in monocytes, Mfs, PMNs, platelets, NK cells, and B cells
FcγRIII	a	NK cells, Mfs (including mesangial cells), subpopulation of monocytes, mast cells (subset of T cells)
	b	PMNs, IFN-γ-stimulated eosinophils

FcγRs are expressed in myeloid and lymphoid lineages. Data on protein expression are not complete.
DCs, dendritic cells; G-CSF, granulocyte colony-stimulating factor; IFN, interferon; Mfs, macrophages; NK, natural killer; PMNs, polymorphonuclear leukocytes.

FcγRs capable of triggering cellular activation possess intracellular activation motifs, termed *immunoreceptor tyrosine-based activation motifs* (ITAMs), similar to those of B-cell receptors and T-cell receptors.⁶¹ These activating FcγRs (FcγRI, FcγRIIa, and FcγRIIIa) exert nonoverlapping functions that in concert and on interaction with immune complexes lead to their clearance (binding and internalization), as well as tissue injury at sites of immune complex deposition (generation of reactive oxygen species and release of inflammatory mediators).^{61,64,65} Inhibitory FcγRs (FcγRIIb) have extracellular domains that are homologous to their activating counterparts, but their cytoplasmic domains contain an *immunoreceptor tyrosine-based inhibitory motif* (ITIM). Studies have suggested that inhibitory FcγRs modulate thresholds for activation and can terminate activation signals. They play a central role in afferent and efferent immune responses as negative regulators of both antibody production and immune complex-triggered activation.^{66,67} Both stimulatory and inhibitory FcγRs are often coexpressed on the surface of hematopoietic cells, which provides a mechanism to modulate cell activation initiated by stimulatory FcγRs. Cytokines, C5a anaphylatoxin, and intravenous gamma globulin have been shown to alter the balance in the expression of stimulatory and inhibitory FcγRs and thereby modulate immune complex clearance and inflammatory tissue injury.⁶⁸⁻⁷⁰ The structure-function relationships of each receptor family provide a framework for understanding how FcγRs may contribute to disease susceptibility, pathogenesis, and therapeutic intervention in SLE.

FcγRI (CD64), expressed on monocytes, macrophages, and IFN-γ-stimulated polymorphonuclear leukocytes, is distinguished by its three extracellular immunoglobulin-like domains and its high affinity for IgG (see

TABLE 128.6
Human Fcγ receptors and IgG subclass specificity

Fcγ family	FcγR gene	Glycoprotein (kDa)	Affinity for IgG (K _d)	IgG subclass specificity
FcγRI	FcγRIa	72	10 ⁸ -10 ⁹ M ⁻¹	1, 3, 4 >> 2

	FcγRIIIb	50-80	10 ⁷ M ⁻¹	1, 3 >> 4, 2

Table 128.6). It associates noncovalently in the membrane with a homodimer of the γ-accessory chain, a member of the γ/ζ family of signal-transducing molecules, which can also associate with the high-affinity receptor for IgE (FcεRI), the high-affinity receptor for IgA (FcαR), FcγRIIIa (see later), and the T-cell receptor/CD3 complex (although it is distinct from CD3γ). FcγRI, the high-affinity receptor for IgG, is the only FcγR that binds monomeric IgG. FcγRI on monocytes or macrophages may play a part in antigen processing.

Receptors of the FcγRII family (CD32) have low affinity for IgG and interact only with multimeric IgG and IgG-opsonized particles. They are widely expressed and present on most leukocytes and platelets. The FcγRII family has three distinct yet highly homologous genes—*FCGR2A*, *FCGR2B*, and *FCGR2C*—that encode the FcγRIIa, FcγRIIb, and FcγRIIc proteins, respectively, and several alternative splice products, thereby resulting in the expression of six protein isoforms. The three genes are nearly identical in their extracellular domains but highly divergent in their cytoplasmic domains, which determines the effector function mediated by each isoform. Activating and inhibiting receptors differ mainly in the signaling motif in the cytoplasmic domain. FcγRIIa and FcγRIIc contain ITAMs, and they are preferentially expressed in myeloid cells. *FCGR2B* is the only *FCGR* gene encoding an ITIM, the canonic motif for an inhibitory receptor⁷¹ (see Fig 128.20). In addition to different isoforms, at least two allelic forms of FcγRIIa (H131 and R131) and two allelic isoforms of FcγRIIb (I232 and T232) are known. The FcγRIIa alleles differ in two amino acids in the extracellular domain, are expressed codominantly on polymorphonuclear leukocytes, and have differing IgG subclass binding specificities.⁷² The FcγRIIb alleles vary in two amino acids in the transmembrane domain, which leads to differences in signal transduction (Fig. 128.21).⁷³

The low-affinity FcγRIII (CD16) family contains two proteins, each with cell-type-specific expression and each encoded by distinct, yet highly homologous genes (*FCGR3A* and *FCGR3B*).⁶¹ FcγRIIIa is the most abundant FcγR on tissue-specific macrophages in the liver and spleen; thus it is a key receptor for immune complex clearance via binding and internalization. In

ALLELIC POLYMORPHISMS OF HUMAN Fcγ RECEPTORS										
FcγRIIa			FcγRIIb			FcγRIIIa		FcγRIIIb

Fig. 128.21 Allelic polymorphisms in the coding region of the human Fcγ receptors FcγRIIa, FcγRIIb, FcγRIIIa, and FcγRIIIb. The R131 and H131 alleles of FcγRIIa have markedly different binding capacities for human IgG2 and murine IgG1 as a consequence of an amino acid substitution in position 131 in the second extracellular domain. The allelic isoforms of FcγRIIb encode an amino acid change in the transmembrane domain (I232 and T232) leading to differences in signaling on coaggregation of FcγRIIb with the B-cell receptor. Polymorphic forms of FcγRIIIa with changes in the sequence at amino acid position 158 result in different binding capacities for all IgG subclasses. The NA1 and NA2 polymorphism of FcγRIIIb, the glycosyl-phosphatidylinositol-linked protein expressed exclusively in neutrophils, reflects four amino acid substitutions resulting in a different number of potential N-linked glycosylation sites (NA1 = 4, NA2 = 6). In contrast to the FcγRIIa and FcγRIIIa polymorphisms, the difference in phagocytic function of the NA1 versus the NA2 alleles does not reflect differences in ligand binding.

addition, it is expressed on dendritic cells, natural killer cells, $\gamma\delta$ T cells, and mesangial cells. FcγRIIIa is a transmembrane protein that most typically associates with a dimer composed of members of the γ/ζ family of signal transduction molecules, which bear ITAMs within their cytoplasmic domains (see Figs. 128.20 and 128.21). These accessory molecules form disulfide-linked dimeric complexes (homodimers or heterodimers) that noncovalently associate with the transmembrane region of FcγRIIIa to enable cell-surface expression and signal transduction. The two allelic forms of FcγRIIIa (F176 and V176) differ in one amino acid at position 176 in the extracellular domain (phenylalanine or valine, respectively),⁷⁴⁻⁷⁶ and they differ in their binding capacity for IgG1 and IgG3 (see Fig. 128.21).

FcγRIIIb provides a dramatic example of structural divergence. It lacks both the transmembrane and cytoplasmic domains and is anchored to the membrane through a glycosyl-phosphatidylinositol moiety. FcγRIIIb is expressed at high levels on neutrophils and is the most abundant FcγR in the circulation. Naturally occurring variations in gene copy number encoding FcγRIIIb have been detected in humans and could constitute a heritable source of susceptibility to autoimmune diseases.^{77,78} Further diversity in FcγRIII structure is provided by an allotypic variation in FcγRIIIb. The two most commonly recognized allelic forms of the glycosyl-phosphatidylinositol-anchored neutrophil isoform of FcγRIIIb, termed NA1 and NA2, differ by several amino acids and N-linked glycosylation sites⁷⁹ (see Fig. 128.21).

Fcγ receptors and systemic lupus erythematosus

The importance of FcγRs in clearance of immune complexes has been shown in a number of different *in vivo* models (see Fig. 128.18); it is likely that both intrinsic (genetic) differences and acquired differences in all three families of FcγRs contribute to net function. For example, experimental blockade of FcγRIIIa by infusion of an anti-FcγRIII monoclonal antibody in both human and nonhuman primates (chimpanzee) inhibits the clearance of IgG anti-D-sensitized erythrocytes, soluble DNA/anti-DNA immune complexes, and to a lesser degree, erythrocyte-bound DNA/anti-DNA immune complexes.⁸⁰ The prolongation of FcγR-mediated clearance of IgG-opsonized erythrocytes by the mononuclear phagocyte system in normal disease-free donors with HLA-DR2 and HLA-DR3 (the same DR alleles associated with SLE) relative to other normal disease-free donors supports a genetic mechanism.⁵⁸

Germline differences in FcγR structure, expression, or function provide the basis for differences in FcγR function between individuals, and these differences may contribute to disease susceptibility and pathogenesis. Review of FcγR deficiencies⁶¹ has revealed the rare association of complete FcγRIIIb deficiency on neutrophils with SLE. More commonly detected are variations in FcγRIIIb gene copy number. The importance of copy number variation is underscored by the strong association between low FcγRIIIb gene copy number and SLE, a mechanism attributed to impaired uptake and

clearance of immune complexes as a result of reduced FcγRIIIb expression on neutrophils.⁷⁸

Currently, several FcγRs have recognized allelic polymorphisms that influence the functional capacity of the receptors⁶¹ (see Fig. 128.21). The FcγRIIa polymorphism (H131, R131) and the FcγRIIIa polymorphism (F158, V158) affect ligand binding—the H131 allele of FcγRIIa is the only FcγR that binds human IgG2 to any appreciable extent. Because IgG2 is a poor activator of complement, FcγRIIa H131 is essential for handling IgG2 immune complexes. A nonsynonymous T/C single nucleotide polymorphism in the *FCR2B* gene that results in a change in an isoleucine to threonine at position 232 in the transmembrane domain of the FcγRIIb protein excludes the receptor from lipid rafts and alters inhibitory function in B cells.^{81,82} Each of these polymorphisms establishes the precedent for genetically determined, functionally important alleles of FcγRs that influence cell triggering and may provide important models for risk factors in disease pathogenesis.

Genetic linkage studies in families in which several members have SLE indicate linkage of the SLE phenotype with a region of human chromosome 1 (1q20-23), the same region that contains the genes that encode all the FcγRs and the associated γ chain (see Chapter 127). Association studies indicate that the low-binding FcγRIIa R131 and FcγRIIIa F176 alleles are enriched in some groups of patients with SLE,^{72,76,83-86} thus suggesting that patients with the potential for less efficient immune complex clearance are at greater risk for immune complex deposition. Indeed, genomewide association studies have confirmed the association of FcγR alleles with SLE.^{72,74,87} Meta-analyses have shown that the FcγRIIa R131 allele is associated with SLE, especially in black individuals, and that the FcγRIIIa F176 allele is associated with SLE in white individuals and in other groups.^{88,89} The association of FcγRIIIa low-binding alleles may be a most important risk factor for lupus nephritis.⁹⁰

The qualitative nature of the immune response is an important principle in all association studies. Differences in the IgG subclass of pathogenic autoantibodies may influence the relative importance of FcγR alleles in disease. For example, in the presence of anti-C1q antibodies, which correlate with severe renal disease and are largely of the IgG2 subclass, *FCGR2A* genes appear to play a crucial role in determining disease severity.^{91,92} IgG2 is the predominant IgG subclass found in the glomeruli of patients with proliferative nephritis, and the frequency of genotypes containing the low-binding IgG2 allele FcγRIIa R131 was significantly greater than expected in patients with class III or class IV nephritis and in patients with intense IgG2 deposition. C-reactive protein, a ligand with particular affinity for the FcγRIIa R131 allele, was consistently present in the renal immune deposits of lupus nephritis specimens.⁹³

Polymorphisms in FcγRIIb that alter signaling (FcγRIIb 2321/T) and variations in the promoter that alter gene expression are associated with

SLE^{73,94,95} (see Fig 128.21). In addition, homozygosity of the hypofunctional allele associated with SLE (the minor allele) is protective against severe malaria.^{96,97} Meta-analysis of association studies of this variant of *FCGR2B* in SLE demonstrated an association of the I87T allele in Asian and perhaps white populations.^{96,98} It is highly likely that additional polymorphic candidate genes are present within this region of chromosome 1.

Acquired differences in receptor expression and function contribute to disease-associated differences in immune complex clearance (see Fig 128.19). The cytokines elaborated during an immune response alter FcγR expression and functional capacity as described later.^{68,99} They differentially regulate the expression of FcγR isoforms with opposite functions, those with ITAMs and ITIMs. This modulation of effector cell function contributes to differences in immune complex handling in SLE.

COMPLEMENT AND Fcγ RECEPTOR FUNCTION: TARGETS FOR TREATMENT

The extensive structural diversity of human FcγRs and the complement system, their importance in immune complex clearance, and evidence of their dysfunction in SLE present the opportunity for novel treatment strategies. Various therapeutic strategies might facilitate handling of immune complexes. Among potential strategies, tissue-specific, cytokine-mediated regulation of FcγR and complement receptor expression might enhance binding and uptake by phagocytes. Administration of complement components might be beneficial in the setting of complete complement component deficiency and lupus-like illness. Blockade of activating FcγRs or co-stimulation of FcγRIIb could alter the threshold of inflammatory effector responses.

Differential regulation of expression of isoforms with opposite functions provides a mechanism for regulation of the signals delivered to effector cells. Cytokines regulate total receptor expression, modulate relative isoform predominance, and thus modulate cellular responses. Specifically, IFN-γ and granulocyte colony-stimulating factor upregulate the expression of different stimulatory FcγRs on monocytes, whereas IL-4 and IL-13 downregulate the expression of all three classes of ITAM-bearing stimulatory FcγRs. In contrast, IL-4 and IL-33 increase and IFN-γ decreases the expression of inhibitory FcγRIIb on monocytes.^{68,99} The complement split product C5a generated at sites of immune complex-triggered inflammation also alters the balance of FcγR by upregulating stimulatory FcγRIIIa expression and downregulating inhibitory FcγRIIb expression on macrophages, thereby lowering the threshold for activation of effector cells and augmenting immune-mediated tissue damage.⁶⁹ Because immune complexes can either enhance or suppress the humoral immune response, depending on the type of FcγR engaged

(stimulatory or inhibitory) and the cell type involved (B cells or antigen-presenting cells), alterations in the balance of FcγR expression can also influence afferent responses.^{53,63} The opportunities for therapeutic intervention are indeed many.

Open studies of intravenous immunoglobulin (IVIG) infusion have been reported for SLE and other rheumatic diseases, but the mechanisms (e.g., blockade of FcγRs, induction of inhibitory FcγRs, binding to antiinflammatory lectin receptors, occupancy of FcγRs, idiotype interactions with autoantibodies, or scavenge complement activation fragments), the indications, and the efficacy of this approach require further study.¹⁰⁰ The antiinflammatory activity of IVIG is attributed, at least in part, to a small fraction of Fc-sialylated IgG molecules that engage the receptor DC-SIGN on a subset of monocytes and cause upregulation of the inhibitory receptor FcγRIIb, thereby protecting against autoantibody-mediated pathology.¹⁰¹

Emigration of neutrophils to inflammatory sites and immune complex-induced acute inflammation can be blocked by decoy FcγR,¹⁰² thus indicating that interventions in the effector stage of immune complex diseases could be accomplished by blocking FcγR or blocking complement activation by enhancing complement regulatory protein function. Early components of complement do not seem to be required for the initiation of inflammatory responses (although they are necessary for clearing apoptotic cells), whereas later components amplify injury, increase the ratio of stimulatory to inhibitory FcγRs expressed,⁷³ and may also act downstream of FcγR activation. By exploiting the intrinsic properties of different FcγRs (e.g., the H131 allele of FcγRIIIa, which binds IgG2, or the V158 allele of FcγRIIIa, which binds IgG with a greater affinity), one could develop a panel of soluble FcγRs with different affinities and subclass preferences that would allow more specific targeting of disease-associated autoantibodies. Changing the glycosylation of IgG is another approach to modulate FcγR-mediated effector formation and interfere with autoantibody-triggered inflammation.^{103,104}

Responses to immune complexes may be modulated by targeted pharmacologic manipulation of protein kinases or phosphatases. Syk inhibitors, which block activating FcγR signaling, are in clinical trials for rheumatoid arthritis and have been shown to suppress skin and kidney disease in lupus-prone mice.¹⁰⁵ Because ITAM signaling is influenced by crosstalk with other signal transduction pathways, such as β₂ integrins and Toll-like receptors (TLRs), these pathways may also be targeted to regulate inflammatory responses.¹⁰⁶ Immune complexes containing nucleosomes engage TLRs and FcγR, and blockade of the cooperative signaling by TLRs on dendritic cells and B cells may alter autoimmune and inflammatory responses.^{107,108}

With our increasing recognition of the role of FcγRs in the pathophysiology of SLE and such a range of receptor-modulating agents, successful therapeutic intervention will be feasible and form the basis of further advances in the treatment of SLE.

Animal models of lupus

■ DAVID I. DAIKH

- A number of inbred mouse strains carry spontaneous mutations that result in clinical, serologic, and immunologic features in common with systemic lupus erythematosus (SLE).
- These strains have been immensely useful for understanding the pathogenesis and genetics of lupus and for predicting effective treatment approaches to human SLE.
- Induced mouse models with features of lupus are increasingly shedding light on the role of individual genes in the pathogenesis of SLE.

INTRODUCTION

The pathogenesis of systemic lupus erythematosus (SLE) is complex and heterogeneous with respect to specific manifestations of the disease in individual patients. The pathogenesis of most disease manifestations has not been completely elucidated. In some cases, disease manifestations result directly from pathogenic autoantibodies. In others, immune responses induced directly or indirectly by antibody-containing immune complexes result in organ damage and dysfunction. The genetics of SLE is similarly complex. Twins and first-degree relatives of patients with SLE are affected more commonly. However, lupus susceptibility is a polygenic trait, and many disease-associated genetic loci have been identified. Hormonal factors have significant effects on disease expression. Environmental factors such as ultraviolet radiation can also have effects on the severity of disease. In addition, some pharmacologic agents can induce autoimmune disease in certain individuals, and drug-induced lupus shares a number of clinical and immunologic features with SLE.

Animal models have been vitally important in developing our understanding of both the normal immune system and the immunopathogenesis of SLE. In fact, most of our advances in understanding the pathogenesis of SLE, either through studies of basic immunology or through studies of genetic susceptibility, have been the result of discoveries made with the use of animal models. Mouse models have been particularly important in this regard. Broad similarities are found between the murine and human immune systems, and the mouse is the major model system used for basic studies in cellular immunology. In addition, the availability of mouse models with many features of SLE has provided an invaluable opportunity for the study of this disease. Countless studies over a 5-decade period have identified clinical, immunologic, and genetic similarities between many murine lupus strains and SLE in humans. Most recently, for example, complex transcriptional network analysis has identified 20 network “nodes” reflecting diverse functions, including immune cell infiltration, endothelial cell activation, tissue remodeling, and macrophage/dendritic cell activation, that are commonly shared between human lupus nephritis and three murine models of lupus nephritis.¹ Murine lupus models can be classified as spontaneous, induced, and engineered models. Spontaneous models include inbred strains in which features of SLE have arisen naturally and congenic strains that result from deliberate crossing and inbreeding of defined lupus-prone strains to genetically isolate particular phenotypic characteristics and subsequently define the associated genetic loci. Induced models include autoimmune or nonautoimmune mice in which autoimmune disease is induced by exposure to chemicals or other defined substances as a model of environmental or drug-induced lupus. Finally, a rapidly growing number of engineered mouse strains are providing important insight into the role of specific immune pathways in the pathogenesis of SLE. These mouse models

of SLE are also frequently used as preclinical models to establish proof of concept for novel therapeutic approaches and to test the specific efficacy of pharmacologic and biologic agents for the treatment of SLE.

SPONTANEOUS MOUSE MODELS

New Zealand black

The spontaneous development of lupuslike features has been identified in a number of inbred mouse strains (Table 129.1).²⁻¹⁰ The earliest of these strains was the New Zealand black (NZB) mouse, which was developed by Dr. Marianne Bielschowsky at the University of Otago Medical School in New Zealand in the process of generating new inbred mouse strains. She found that early mortality developed in these mice because of widespread hemolysis as a result of autoimmune hemolytic anemia. Development of hemolytic anemia in this strain has been linked most specifically to two genetic loci: Aia3 and Nba2. NZB mice have a life expectancy of 16 to 17 months, as opposed to more than 2 years for normal mice. This strain exhibits many manifestations of B-cell hyperreactivity, including hypergammaglobulinemia, an immunologic characteristic of many SLE patients. Late in life, B-cell lymphomas that are similar to the lymphomas that develop in some people with Sjögren syndrome develop in most NZB mice. Kidney disease secondary to immune complex glomerulonephritis also variably develops in NZB mice, but involvement is mild and it develops only slightly earlier in female mice than in males.

(NZB×NZW)_F₁

Subsequent crosses of the NZB strain with other unrelated strains identified hybrids with additional autoimmune features. The most interesting of these was the cross between NZB and New Zealand white (NZW) mice. NZW mice have a normal to prolonged life span and are generally healthy. However, mating of NZW with NZB mice results in first-generation offspring that have high-titer antinuclear antibodies (ANAs), aggressive kidney disease, and early mortality. This (NZB×NZW)_F₁ hybrid (NZB/W) became the first and best characterized mouse model of SLE, and studies in this strain provided many important early insights into the pathogenesis of autoimmunity.² High-titer double-stranded DNA (dsDNA) antibodies and kidney disease with many features of lupus nephritis, including proliferative glomerulonephritis, develop in NZB/W hybrids. Renal disease is the major cause of the early mortality in this strain¹¹ (Fig. 129.1). Characteristic lupus erythematosus cells (LE cells), a pathologic hallmark of SLE, also develop in NZB/W mice. Circulating autoantibodies and clinical renal disease appear earlier in female B/W mice than in males, and like humans with SLE, the disease is more severe in female mice. Although renal disease is the most obvious clinical manifestation of disease in NZB/W mice, other organs are also involved, including the exocrine salivary glands; sialadenitis and generalized lymphadenopathy mimicking Sjögren syndrome, a frequent secondary complication of SLE, develop in the salivary glands. These mice also appear to have central nervous system (CNS) abnormalities in common with SLE, although developmental abnormalities are also present in the brains of NZB/W hybrids and can confound pathologic studies in this strain. Serologic abnormalities common in SLE are also present in this hybrid, including hypergammaglobulinemia, antilymphocyte antibodies, and hypocomplementemia.² B/W mice produce anti-dsDNA antibodies in high titer. Subsets of IgG, particularly IgG2, are nephritogenic in that they not only induce glomerulonephritis and subsequent proteinuria in lupus-prone mice but can also induce glomerular damage when infused into normal BALB/c mice. Other autoantibodies detectable in NZB/W mice include antinucleosome

Fig. 129.1 (a) Seven-month-old diseased mouse on the right with fluid retention versus a 3-month-old healthy mouse on the left. (b) Graph showing the percentage of patients in whom proteinuria develops as a result of glomerulonephritis (red) and percent survival (blue). (c) Renal pathology includes inflammation, glomerulonephritis, and tubular dilation. (d) Glomerular immune complex deposition in the mouse kidney.

and antihistone antibodies. As noted, the switch to IgG2 is characteristic of the autoantibodies in NZB/W mice as opposed to NZB mice, and many of them are complement-fixing isotopes. Thus, the development of IgG autoantibodies is linked to the hypocomplementemia that develops in this strain. Early expansion of CD5+ (B1) B cells also occurs in NZB and NZB/W mice and correlates with the development of autoantibodies. Elimination of these cells reduces autoantibody levels and substantially prolongs life. These cells are increased in the NZB parental strain as well. A distinguishing feature of CD5+ B cells in both strains is that they frequently exhibit aneuploidy, which appears to be the major factor leading to B-cell lymphomas in both strains. NZB/W mice also have abnormalities in professional antigen-presenting cells (APCs) when compared with nonautoimmune mice. Dendritic cells are increased in diseased mice and have altered expression of co-stimulatory receptors.¹² They also effectively co-stimulate T cells to produce antinucleosome autoantibodies.¹³ These cells produce increased amounts of type I interferons in comparison to controls, which is another immunologic feature shared by this model and SLE in humans.^{14,15} The increasing number of studies relating type I interferons to the pathogenesis of SLE and the observation that interferon- α (IFN- α) worsens disease in NZB/W mice suggest that dendritic cells are a significant factor in the

pathogenesis of autoimmunity in this model. Despite the relationship between B-cell hyperactivity, autoantibody production, and disease, it is clear that lupus is a T cell-dependent disease in these strains. Depletion of CD4+ T cells with monoclonal antibodies prevents the development and progression of disease, and the switch to pathogenic IgG anti-DNA antibodies in B/W mice is T cell dependent.^{11,16} Less clear is the function of regulatory T cells in this model. Foxp3-expressing CD25+ regulatory T cells function in normal mice and humans to maintain peripheral tolerance by suppressing autoreactive T cells and APCs. These cells are present in lower numbers in young prediseased B/W mice than in age-matched BALB/c mice, but their numbers increase significantly with the development of autoimmune disease.¹⁷ These regulatory cells have been variably reported to have normal or decreased suppressor function *in vitro*.^{18,19} However, adoptive transfer of activated CD25+ regulatory T cells retards the progression of active renal disease in NZB/W mice.¹⁷ Thus, although it is not clear whether NZB/W lupus-prone mice have an intrinsic defect in the regulatory T-cell compartment, it appears that they can be induced to suppress autoimmune disease.

The NZB/W model has also been valuable for studies of the mechanisms responsible for the female preponderance of autoimmune disease in humans. Castration of NZB/W mice early in life result in more severe disease that parallels that of female mice, whereas castration of female mice has no effect on the course of disease.²⁰ On the other hand, treatment of female NZB/W mice with androgens limits disease, whereas estrogens accelerate disease. Interestingly, androgens can ameliorate lupus nephritis and prolong survival in NZB/W female mice with advanced disease.²⁰ Thus, the more severe pattern of disease in NZB/W mice can be explained almost entirely by the effect of sex hormones.

As expected from the multiple immunologic abnormalities identified in NZB/W mice, the genetics of autoimmunity in these mice is complex. Genomewide linkage studies in NZB- and NZW-related strains indicate that more than 20 loci influence disease susceptibility or expression (or both). As with human SLE, the major histocompatibility complex (MHC) locus is clearly of importance for disease susceptibility. The major MHC contribution is from the H-2^z locus on chromosome 17 of the NZW parent, but many non-MHC loci are important in the pathogenesis of lupus. One such region identified in NZB mice is the Nba2 locus.²¹ This region contains the interferon-inducible gene *Ifi202*, which is linked to the production of nuclear autoantibodies, including those to native DNA. The effect on autoantibody production appears to be the result of enhanced survival of B cells mediated by *Ifi202*. The implication of a lupus susceptibility gene in NZB autoimmune-prone mice that is regulated by type I interferons is interesting

in light of the increasing evidence in support of a role for interferon-inducible genes in SLE.¹⁵

The value of the NZB/W strain as a model of SLE is also supported by a large number of preclinical studies in NZB/W mice demonstrating the efficacy of immunosuppressive and immunomodulatory agents in ameliorating autoimmune disease. In fact, the efficacy of the major agents currently used to treat SLE was first established in NZB/W mice, including corticosteroids, cyclophosphamide, cyclosporine, and mycophenolate mofetil.²²⁻²⁵ This model is also commonly used to test the efficacy of novel treatment strategies for SLE. Recent examples include antibodies or soluble receptors that block co-stimulatory signals between T cells, APCs, and B cells^{7,8,26-29}; B-cell stimulatory factors^{30,31}; antibodies against immunomodulatory cytokines; and small-molecule inhibitors of immune receptor signaling.³² Other lupus models have also been used to test *in vivo* preclinical efficacy, most commonly in the MRL/lpr³³ and SNF1³⁴ models described later.

New Zealand mixed strains

Progressive inbreeding of NZB/W hybrids to select for severity of kidney disease and coat color produced a group of hybrid strains referred to as New Zealand mixed strains.³ These strains have been used to isolate and characterize specific disease susceptibility loci in the NZB and NZW genomes. The NZM2410 strain, in which high-titer ANAs and aggressive glomerulonephritis develop, has been particularly useful in segregating specific disease characteristics. Backcrossing of specific NZM2410 lines onto the nonautoimmune C57BL/6 background produced hybrid strains that are congenic for different disease susceptibility loci.⁴ The three major loci have been designated Sle1, Sle2, and Sle3/5. Selective crossing of these congenic strains has demonstrated the phenotypic characteristics of each of these genetic loci. Sle1 mediates the loss of tolerance to nuclear autoantigens, including chromatin. Nephritis results when Sle1 is combined with Sle2 or with Sle3/5.³⁵ These data have been interpreted to suggest that the pathogenesis of murine lupus is a multistep process in which the disease is initiated by a gene or genes within the Sle1 locus and then worsened by additional susceptibility genes. Sle2 confers a significant proportion of the B-cell hyperactivity seen in NZB/W mice,³⁶ whereas Sle3 is associated with generalized T-cell activation.³⁷ The Sle3/5 locus appears to contribute to the increased activity of APCs.³⁸ More recently, selective breeding of Sle1 congenic strains has indicated that disease susceptibility is conferred by four subintervals (Sle1a to Sle1d). Detailed mapping of these intervals suggests that polymorphisms in the SLAMF2 gene cluster confer susceptibility at the Sle1b locus and that polymorphisms in the C2 gene confer susceptibility at the Sle1c locus.^{39,40}

SNF1

The SNF1 mouse model (SWR×NZB)_F₁ is another lupus-prone strain derived from the autoimmune NZB strain. Like NZB/W mice, both anti-DNA and antinucleosome antibodies and female-predominant glomerulonephritis develop in SNF1 mice and lead to death by 1 year of age.⁵ The SWR parent is not autoimmune prone and has a normal life span. NZB loci contributing to disease in this hybrid strain include Nba1 and Nba3, whereas probable genetic susceptibility loci contributed from SWR include the T-cell receptor-β (TCR-β), I-A, and Swrl genes.⁴¹ The SNF1 strain has provided much information about the role of nucleosomes as autoantigens and the role of cationic anti-DNA autoantibodies in the pathogenesis of autoimmune kidney disease.⁶ The specificity of the antinucleosome response in SNF1 mice has also been instructive. The autoepitopes for pathogenic T-cell clones derived from SNF1 mice have been mapped in core histones with the use of overlapping synthetic peptides. One of these peptides is homologous to histone H1'₂₂₋₄₂ and stimulates T helper (Th) cells to augment the production of pathogenic autoantibodies. Importantly, a marked expansion of H1'₂₂₋₄₂-reactive Th1 cells occurs early in life in SNF1 mice, and this peptide accelerates glomerulonephritis in SNF1 mice more potently than do other identified nucleosomal epitopes.²⁸

MRL/lpr and MRL/gld

The MRL/lpr mouse has been an informative model of systemic autoimmunity, particularly because it led to the identification and characterization of a single gene that markedly accelerates murine lupus. The parental MRL strain (MRL/mp) was originally established from crossing several standard inbred strains. After multiple generations of MRL/mp, massive lymphadenopathy and splenomegaly were noted to develop in the offspring from one mating. An autosomal recessive mutation was identified and designated *lpr* for lymphoproliferation.⁷ This mutation was localized to chromosome 19. Severe manifestations of autoimmune disease with high-titer autoantibodies

and significantly more aggressive glomerulonephritis were also found to develop in the MRL/lpr mouse. MRL/lpr mice produce antibodies to DNA and ribonuclear proteins, including Sm. The *lpr* defect represents a mutation in the gene that encodes the Fas protein.²⁹ Fas is a type I membrane protein member of the tumor necrosis factor receptor family that is expressed on activated lymphocytes and in the thymus and transduces an apoptotic signal. Definitive demonstration of the role of Fas in MRL/lpr mice was provided by an experiment in which normal Fas protein expressed from a transgene prevented the lymphoproliferative disease. Another autosomal recessive mutation resulting in a very similar phenotype as the *lpr* mutation was identified in the inbred C3H/HeJ strain. This mutation was localized to chromosome 1 and designated *gld* for generalized lymphoproliferative disease. Bone marrow transplant experiments between wild-type MRL mice and *lpr* and *gld* mutant mice established that the *lpr* and *gld* genes represent a receptor-ligand pair of molecules, and thus *gld* represents a mutation in Fas ligand.⁸ The *lpr* mutation in MRL/lpr mice can be viewed as an epigenetic or accelerating factor for systemic autoimmunity. Massive nonmalignant lymphoproliferation and early mortality develop in MRL/lpr mice, as well as several manifestations of autoimmunity, including glomerulonephritis, vasculitis, and arthritis with variable penetrance, in addition to autoantibody production. This lymphocyte expansion and infiltration are predominantly due to accumulation of immature “double-negative” (DN) T cells lacking CD4 and CD8. Accumulation of these DN T cells in the periphery is not due to abnormal proliferation but rather to loss of their usual programmed cell death. MRL/lpr mice also appear to have B-cell abnormalities associated with autoantibody production. Although lymphoproliferation is the distinguishing feature of MRL/lpr mice, this model has a number of clinical manifestations that are similar to those seen in other murine lupus models and humans with SLE, including glomerulonephritis with complement deposition; necrotizing vasculitis of medium-sized arteries, particularly the renal, mesenteric, and coronary arteries; interstitial pneumonitis; and skin disease. MRL/lpr mice also display signs of CNS involvement. The severity of disease, as well as the range of autoantibodies produced, is dependent on the genetic background on which the *lpr* mutation is expressed. These autoimmune manifestations in *lpr/lpr* mice are most prominent on the MRL background. This strain has also been used frequently to examine the efficacy of therapeutic interventions for SLE.^{42,43}

BXSB

The BXSB mouse is another spontaneous model in which anti-DNA antibodies and immune complex glomerulonephritis develop, as in NZB/W and MRL/lpr mice.⁴⁴ However, BXSB mice are unique among murine models of SLE in that male mice are more severely affected than females. In this model, genetic factors on the Y chromosome rather than hormonal influences accelerate disease in male mice. This factor can act independently of genetic background in that in crosses of BXSB with other autoimmune strains, lupuslike disease develops in *F*₁ male mice with an onset and phenotype like that of BXSB males. However, crosses of BXSB mice with nonautoimmune strains does not lead to autoimmune disease in male offspring. Thus, the Y-linked gene acts as a disease-accelerating factor, but autoimmunity-predisposing background genes are also required for the development of autoimmunity. This was dramatically demonstrated in an experiment in which fatal immune complex-mediated glomerulonephritis developed in otherwise normal mice expressing both *Yaa* and the Sle1 locus. The Y-linked gene is called *Yaa* (Y-linked autoimmunity accelerator). The *Yaa* gene in BXSB has recently been shown to be a duplication of the Toll-like receptor 7 (TLR7) gene, which results in overexpression of TLR7.^{9,10} TLR7 is the innate immune receptor for single-stranded RNA, and overexpression of TLR7 appears to preferentially induce B cells to produce autoantibodies, particularly to nuclear antigens, including single-stranded DNA (ssDNA), dsDNA, and chromatin. As in other murine lupus models, BXSB B cells exhibit an activated phenotype and are hyperproliferative such that B-cell expansion occurs in this strain, except that it is more marked in male animals. Yet as is the case in other murine lupus models, disease in BXSB mice is also dependent on T cells, and disease can be suppressed by treatment with anti-CD4 monoclonal antibody or by blockade of T-cell co-stimulation with CTLA4Ig.⁴⁵

INDUCED MODELS

Spontaneous murine lupus models with clinical and immunologic features of SLE have proved valuable for dissecting pathogenic mechanisms and ultimately for clarifying the genetic basis for systemic autoimmunity. However, there are an increasing number of examples in which autoimmune

disease can be induced in nonautoimmune strains. In some cases these models have shed light on potential mechanisms by which environmental exposure can contribute to the development or severity of lupus. For example, cutaneous lupuslike skin lesions can be induced in TCR- α -deficient mice treated with 5-fluorouracil (5-FU) plus ultraviolet B (UVB) light. These skin lesions have several features characteristic of chronic cutaneous lupus erythematosus, including CD4+ cell infiltration and IgG deposition at the dermal-epidermal junction. Lesions in these mice appear more rapidly and are more severe than lesions that develop in C57BL/6 mice treated with the same dose of UVB light and 10 times more 5-FU. CD4+ cells are required for the development of this skin lesion.⁴⁶

Pristane-induced lupus

Kuroda and colleagues⁴⁷ extensively characterized the lupuslike autoimmunity induced by intraperitoneal injection of the hydrocarbon pristane (2,6,10,14-tetramethylpentadecane) in mice. Autoimmune disease in this model is characterized by autoantibody production and renal immune complex deposition with complement activation. Remarkably, such exposure induces the production of autoantibodies in nonautoimmune strains as well as in autoimmune susceptible strains, although the level of induction, severity of disease, and range of autoantibody specificity are influenced by the genetic background. For example, in response to intraperitoneal pristane, autoantibodies to histones, Sm, Su, dsDNA, and collagen develop in BALB/c mice, whereas SJL/J mice predominantly produce antibodies to ribosomal P protein. The development of autoantibodies and clinical renal disease induced by pristane is dependent on TLR4 and TLR9.⁴⁸ Pristane can also produce inflammatory arthritis in some susceptible strains.

Much effort has been devoted to inducing autoimmune disease in murine models through exposure to known autoantigens such as DNA and RNA. These nucleic acids are more immunogenic when coupled to or associated with protein. For example, nucleosome particles are generally more effective than free DNA in inducing anti-DNA antibodies and ANAs in normal or autoimmune strains. However, bacterial-derived DNA that contains the CpG motif is more effective in inducing autoantibodies in mice, and administration of CpG-containing oligonucleotides can produce autoantibody-mediated immune complex glomerulonephritis.⁴⁹ CpG DNA activates B cells directly.⁵⁰ Signals from these foreign antigens are transduced via the TLR9 receptor and may be important adjuvants in stimulating autoreactivity in humans, in addition to serving as autoantigens.⁵¹

A number of induced murine models of organ-specific autoimmune disease have also been developed, such as experimental autoimmune nephritis.⁵² A very interesting model of autoimmune-mediated CNS disease has been developed by using passive transfer of brain-reactive autoantibodies combined with procedures that break the blood-brain barrier in mice. This model has provided new insight into the pathogenesis of brain dysfunction in SLE, including cognitive dysfunction, memory loss, and emotional disturbance.⁵³

ENGINEERED MOUSE MODELS

Genetically engineered mouse models are increasingly providing important clues to the pathogenesis of lupus through identification of the functions of specific components of the immune system in the context of autoimmune susceptibility (Table 129.2).⁵⁴⁻⁶⁵ Molecular cloning and recombinant DNA techniques coupled with transgenic technologies have provided the ability to modulate normal gene expression by increasing or decreasing normal levels of expression of a specific gene or even by inserting an entire functioning gene into a different genetic background to examine its function *in vivo*. For example, overexpression of genes that promote lymphocyte survival, including *Bcl2* and *BAFF*, leads to the development of autoimmunity and lupuslike phenotypes.^{65,66} Alternatively, specific genes can be rendered nonfunctional via targeted deletion or insertion of a DNA segment to “knock out” the gene. This latter approach has been useful in implicating several diverse pathways in the development of SLE. From such experiments it has become clear that loss of function of any of a large number of single genes can lead to immunologic and pathologic changes similar to those observed in lupus. Examples of single gene defects leading to loss of negative regulation of lymphocyte activation include CTLA-4,^{54,55} CD22,⁵⁶ CD31,⁵⁷ Fyn,⁵⁸ Lyn,^{59,67} FcγRIIB,⁶⁰ PTEN,⁶¹ PD-1,⁶² and PKC-δ.⁶³ The value of such *in vivo* studies is illustrated by studies of the *lyn* knockout mouse, which has clarified the role of this gene in the B-cell hyperactivity observed in murine and human lupus, as well as emphasized the complexity of this autoimmune phenotype. Thus, in mice deficient in *lyn*, which negatively regulates B-cell activity, increased plasma cells and autoantibodies develop. However, even

though the development of IgG autoantibodies depends on interleukin-6, the accumulation of plasma cells and autoreactive IgM does not.⁶⁴ Another example of how engineered models can illuminate the importance of specific genes in normal and autoimmune responses comes from studies of the function of the lymphocyte-activating protein CD45. CD45 is a protein tyrosine phosphatase that plays a key role in receptor-activated signal transduction in lymphocytes, including integration of signals from cytokines and co-stimulatory molecules, and it is required for normal lymphocyte development. Dimeric CD45 is maintained in an inactive state when a wedge-shaped domain from one homodimer is inserted into the catalytic site of the other homodimer. Polyclonal lymphocyte activation, lymphoproliferation, autoantibody production, and autoimmune glomerulonephritis develop in mice with a targeted single point mutation that inactivates this inhibitory wedge of CD45.⁶⁸ This *in vivo* genetic study in an engineered mouse model is another example of how loss of negative regulation of lymphocyte activation can lead to autoimmune disease, and it demonstrates the importance of precise lymphocyte regulation in maintaining tolerance and preventing a shift in balance to the development of autoimmunity. It also illustrates how a very small genetic change can upset this balance. Genes involved in clearance of the products of cellular apoptosis, including DNA (DNase I and caspase-activated DNase), chromatin (serum amyloid P), and cellular proteins (C1q), have also been studied *in vivo* by targeted deletion. In each case, antinuclear autoantibodies and immune complex glomerulonephritis develop in the knockout mice.⁶⁹⁻⁷¹ Another group of molecules whose importance in lupus has been demonstrated *in vivo* in animal models and subsequently in SLE are the immunomodulatory cytokines, particularly the interferon gene family. For example, lupus nephritis with antinuclear autoantibodies develops in mice transgenic for IFN-γ, and NZB mice deficient in type I interferon receptor exhibit an attenuation of their lupuslike disease.⁷²

An important factor that must be considered when interpreting the results of studies of engineered mouse models of autoimmune disease is the genetic background of the parental strains. In fact, the genetic background can markedly influence the autoimmune lupus phenotype in gene-targeted mice. Thus, there may be variable components of autoimmune susceptibility in some “normal” mouse strains. This possibility has been verified in a study of the 129 mouse strain, which is widely used in the generation of gene-targeted mice.⁷³ This suggests the possibility that background gene influences might account for some of the autoimmune phenotype ascribed to a single gene in knockout mice and highlights the importance of epistatic gene modifiers in shaping the autoimmune phenotype. Epigenetic interactions between female sex, estrogens, and DNA methylation have also been investigated in a novel inducible epigenetic lupus model.^{74,75} MicroRNA is another epigenetic factor that is being recognized as an important factor in immune regulation, as well as in pathologic immune dysregulation. Interestingly, a distinct microRNA expression pattern has recently been identified in common in three different murine models.⁷⁶

Completion of genomewide association studies in human SLE and advances in exome and whole-genome sequencing are currently leading to very rapid progress in the identification of lupus susceptibility genes in

humans. In many cases the identified candidate genes have also been implicated in the pathogenesis of murine lupus.⁷⁷ For example, polymorphisms in the *STAT4* gene confer significant risk, and deficiency of this gene in NZM mouse strains influences disease severity.^{78,79} Similarly, kallikrein genes are associated with lupus nephritis in humans and mouse models.⁸⁰ Despite these rapid advances in the identification of important genes that confer risk for SLE in humans, ongoing mechanistic and genetic studies in mouse

models will continue to be required. The ability to analyze the function of an abnormal gene *in vivo* is critical to unraveling the functional roles of many of these genes, as well as their interactions with each other. These genetic and functional studies in mouse models coupled with *in vivo* evaluation of the effectiveness of new targeted therapies emphasize the vital role of murine models in the ongoing study and development of effective treatments of SLE.

Autoantibodies in systemic lupus erythematosus

■ WESTLEY H. REEVES ■ YI LI ■ HAOYANG ZHUANG

- Some autoantibodies have high diagnostic specificity for systemic lupus erythematosus, particularly anti-Sm, anti-dsDNA, anti-ribosome P, and anti-proliferating cell nuclear antigen autoantibodies.
- The levels of some autoantibodies parallel disease activity.
- Certain autoantibodies are associated with clinical subsets of disease.
- Some autoantibodies may directly or indirectly cause cell or tissue injury.
- Autoantibody production may be induced or maintained by immunostimulatory antigens released from dead cells.
- Autoantibodies are useful tools for cell biologists to explore the function of cellular antigens.

INTRODUCTION

Nearly all patients with systemic lupus erythematosus (SLE) produce autoantibodies. The first evidence of the existence of autoantibodies was Har-Graves' description of the LE cell phenomenon (phagocytosis of intact nuclear material by polymorphonuclear leukocytes) in 1948.¹ Antinuclear antibodies (ANAs) and anti-DNA antibodies were reported in 1957, and autoantibodies to nonhistone autoantigens (anti-Sm antibodies) were first reported in 1966.¹ Over the next 30 years a diverse array of autoantibodies associated with SLE and other systemic autoimmune diseases were identified. This chapter reviews the major autoantibodies associated with SLE, their diagnostic applications and role in disease pathogenesis, and current hypotheses regarding their origins.

ANTINUCLEAR ANTIBODIES

Most autoantibodies produced by patients with SLE recognize nuclear antigens, although antigens located in the cytoplasm or on the cell surface or secreted by the cell may be recognized. The simplest screening assay is the fluorescent ANA assay (Fig. 130.1). With the use of cultured human Hep-2 cells, more than 95% of lupus patients are found to have positive ANA. "ANA-negative lupus" is usually associated with autoantibodies against cytoplasmic autoantigens, such as Ro (SS-A). Although the sensitivity of the fluorescent ANA assay is high, its specificity for SLE is only approximately 20%, with a positive predictive value of 11% to 13%.² Thus, although a negative ANA assay helps exclude lupus, a positive ANA finding is considerably less useful. A positive ANA test may also be seen with other systemic autoimmune diseases, autoimmune thyroid disease, drug-induced lupus, infections, and neoplastic diseases. Some healthy individuals also have a positive result.³ This is highly dependent on the serum dilution and the person's age (frequency increases with age). Although only about 3% of randomly selected healthy individuals are positive at a 1:320 dilution, this value increases to around 30% at a 1:40 serum dilution.¹

Fluorescent ANA assay

Present-day fluorescent ANA tests generally use Hep-2 cells (a human laryngeal carcinoma cell line) as a substrate for testing diluted serum (see Fig. 130.1a). The titer (see Fig. 130.1b) and pattern (see Fig. 130.1c) are reported. Although interpretation is observer dependent, a 1:160 dilution probably yields the optimal balance between sensitivity and specificity. At

this dilution, patients with SLE can be discriminated from healthy controls 95% of the time.

A variety of staining patterns may be seen, most commonly homogeneous, speckled, nucleolar, cytoplasmic, centromere, and proliferating cell nuclear antigen (PCNA) (see Fig. 130.1c). These patterns result from antibodies recognizing different subcellular structures. A homogeneous pattern may be due to anti-DNA or antichromatin autoantibodies, whereas a speckled pattern is frequently associated with autoantibodies against ribonucleoproteins and cytoplasmic staining with autoantibodies to ribosomes, Ro60, or tRNA synthetases. A nucleolar pattern is suggestive of scleroderma, and a centromere pattern is often associated with CREST syndrome (calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia). Variable staining of interphase nuclei is usually due to anti-PCNA.

Alternative techniques for detecting ANAs

Double immunodiffusion

Double immunodiffusion provided early evidence that certain autoantibodies are more specific for the diagnosis of SLE than are ANAs. Autoantibodies detected with high specificity with this technique include anti-Sm, anti-RNP, anti-Ro (SS-A), anti-La (SS-B), anti-topoisomerase I (Scl-70), and anti-Jo-1. Though highly specific, this assay is labor-intensive and has been replaced largely by enzyme-linked immunosorbent assays (ELISAs) and multiplex bead assays, which can be automated and are more quantitative (Fig. 130.2a and b).

Enzyme-linked immunosorbent assay

The ELISA technique detects binding of the patient's immunoglobulin to antigens immobilized on plastic wells (see Fig. 130.2a).

Crude nuclear extracts have been used in ELISA to substitute for the fluorescent ANA test, but the binding of different antigens is variable, and mixtures of purified or recombinant antigens are used more often. The limitation is that autoantibodies reactive with antigens not included in the mix will not be detected. ELISAs are widely used in automated testing for antibodies against single autoantigens and generally perform acceptably in this setting. However, both false-positive and false-negative results occur, so the test results must be interpreted in light of the clinical situation.

Multiplex bead assays

In multiplex bead assays, individual autoantigens (e.g., RNP, Sm, Ro60) are conjugated to different-colored fluorescent microspheres, followed by incubation with serum and fluorescently tagged secondary antibodies (see Fig. 130.2b). These assays reliably detect autoantibodies against multiple analytes in a single test. However, only antibodies against components of the antigen mix used in the assay can be detected. Thus, these assays provide different information than that provided by the fluorescent ANA test. The fluorescent ANA test is the best screening method but provides limited information about autoantibody specificities. In contrast, multiplex bead assays are less sensitive than the fluorescent ANA test for screening but provide useful information on the types of autoantibodies present in a patient's serum.

Western blot assays

Western blotting involves dissociating cellular antigens in detergents, separating them by size via gel electrophoresis, and transferring them to a membrane. A modification of the Western blot strategy has been used to identify, clone, and express genes encoding lupus autoantigens (see Fig. 130.2c).

Fig. 130.1 (a) Hep-2 cells are grown on a microscope slide, fixed/permeabilized, and then incubated with a patient's diluted serum. After washing off unbound serum, the cells are incubated with fluorescently labeled goat antihuman IgG antibodies before viewing with an epifluorescence microscope. (b) Antinuclear antibody (ANA) titer. Patient serum is diluted 1:40, and then serial twofold dilutions are used to stain Hep-2 cells. In the example there is a weak fluorescent signal at a 1:320 dilution and no staining at 1:640 (a 1:320 titer). (c) ANA patterns. Illustrated are the staining patterns of anti-DNA antibodies (homogeneous), anti-RNP (speckled nuclear), anti-RNA polymerase I/III (nucleolar), anti-Jo-1 (cytoplasmic), anticentromere, and anti-proliferating cell nuclear antigen (PCNA) (variable intensity).

Immunoprecipitation assays

Immunoprecipitation of radiolabeled cell extracts is an important research tool used to define the components of autoantigens and to detect autoantibodies (Fig. 130.3). Immunoprecipitation assays have shown that many of the major autoantigens contain nucleic acid (DNA or RNA) components plus proteins (Fig. 130.4).

AUTOANTIGENS AND CLINICAL SIGNIFICANCE OF AUTOANTIBODIES

Through the use of immunoprecipitation, Western blotting, and recombinant autoantigen-based assays, autoantibodies specific for SLE, systemic sclerosis (SSc), polymyositis/dermatomyositis (PM/DM), rheumatoid arthritis (RA), or other clinical subsets have been identified and their cognate autoantigens characterized (Table 130.1; see also Fig. 130.3b).

Fig. 130.2 (a) Enzyme-linked immunosorbent assay. The wells of a 96-well microtiter plate are coated with antigen (step 1), followed by the sequential addition of diluted patient serum (step 2), enzyme-labeled goat antihuman IgG secondary antibody (step 3), and substrate (step 4). Colored product is quantified with a spectrophotometer. (b) Multiplex bead assay. Fluorescently tagged microbeads coated with different antigens (in this example, RNP, Sm, and Ro60) are incubated with diluted patient serum followed by goat antihuman IgG antibodies labeled with a different fluorescent dye. Binding of antibodies to each of the differently labeled antigen-bearing beads is determined with a laser detector. In this example, the patient's serum autoantibodies bind only to the anti-RNP beads. (c) Adaptation of the Western blot procedure to clone autoantigen genes. A Petri dish with a lawn of bacteria is infected with a human cDNA library in bacteriophage γ gt11, an expression vector that allows the inserted human genes to be expressed as protein. A replica of the plaques is made by blotting onto a nitrocellulose filter impregnated with an inducer of gene expression, which is then incubated sequentially with diluted patient serum containing an autoantibody of interest and enzyme-labeled secondary antibody. A colored reaction product is deposited over one of the replica plaques to allow that plaque to be purified from the Petri dish. The gene of interest is excised from the bacteriophage, cloned into a plasmid expression vector, and used to generate large amounts of recombinant human protein in *Escherichia coli*.

ANALYSIS OF AUTOANTIGENS AND AUTOANTIBODIES BY IMMUNOPRECIPITATION

Fig. 130.3 (a) Tissue culture cells are grown in culture medium containing a radioactive amino acid. Cell extract is prepared and incubated with protein A-Sepharose beads preincubated with a patient's serum. Cellular antigens recognized by the serum autoantibodies become attached to the beads, and unbound proteins are washed away. The radioactive proteins are eluted from the beads and analyzed by sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE), followed by exposure to an x-ray film (autoradiography). (b) SDS-PAGE analysis of serum samples. Red arrowheads depict ribosomal P antigens (P0, P1, and P2). These antigens also are immunoprecipitated by the anti-Sm serum in lane 1: anti-Sm immunoprecipitates A-G (green arrowheads) and anti-ribosomal P precipitates P0, P1, and P2. N, normal human serum.

Sm and RNP autoantigens

Anti-Sm and anti-RNP autoantibodies recognize a set of small nuclear ribonucleoproteins (snRNPs) containing uridine-rich small RNA (U1, U2, U4, U5, and U6 RNA) involved in splicing messenger RNA (Table 130.2). All of these contain a group of proteins known as the "Sm core particle" (proteins B', B, D1, D2, D3, E, F, and G), which forms a donut-shaped ring surrounding the RNA strand recognized by the anti-Sm antibodies (see Fig. 130.4a). Along with a single molecule of U1, U2, U4/U6, or U5 RNA, individual snRNPs contain unique proteins: 70K, U1A, and U1C (reactive with anti-RNP antibodies) in the case of U1 snRNPs (see Fig. 130.4a) and 200/205-kDa proteins (U5-205K) in the case of U5 snRNPs. These structures explain the patterns in Figure 130.3b. Anti-RNP antibodies immunoprecipitate the U1 snRNP as an intact particle, and proteins A, B'/B, C, D1/D2/D3, E, F, and G (70K labels poorly) appear in the "RNP" lane (see Fig. 130.3b). Anti-Sm sera also immunoprecipitate proteins A to G, but because all U snRNPs contain the Sm core particle, U5-205K proteins are also present (see Fig. 130.3b, "Sm").

Anti-Sm antibodies are detectable in 10% to 25% of unselected lupus sera, but the prevalence is higher in black than in white patients with SLE (Fig. 130.5). Anti-Sm antibodies are found only in SLE, whereas anti-RNP antibodies are seen in SLE, as well as in other systemic autoimmune disorders.¹ Anti-Sm antibodies are virtually always associated with anti-RNP. In contrast, anti-RNP antibodies are often present without anti-Sm, a pattern characteristic of mixed connective tissue disease. Levels of anti-RNP are generally higher than those of anti-Sm. Usually, autoantibodies are produced against more than one of the protein components of the U1 snRNP, and about 40% of sera contain autoantibodies against the U1 small RNA.⁴

Ro60 (SS-A) and La (SS-B) autoantigens

Anti-Ro (SS-A) antibodies recognize a set of primarily cytoplasmic RNPs consisting of the 60-kDa Ro60 antigen and a single molecule of human Y1, Y3, Y4, or Y5 RNA (see Figs. 130.3b and 130.4b). The 47-kDa La (SS-B) antigen associates transiently with precursors of the small RNAs synthesized by RNA polymerase III, including Y RNA, which protects them from exonucleases.¹ La is a termination factor for RNA polymerase III.

Ro60 also binds misfolded RNA and plays a role in quality control of U2 and 5S ribosomal RNA.⁵ It may confer protection against ultraviolet irradiation by promoting the degradation of damaged (misfolded) RNA. Like the Sm core particle, Ro60 antigen forms a donut-shaped structure through which single-stranded RNA passes. A lupus-like syndrome develops in mice deficient in Ro60, thus raising the possibility that Ro plays an important role in preventing autoimmunity (see later).⁶

Although autoantibodies against the 52-kDa Ro52 protein are strongly associated with anti-Ro60 and anti-La (SS-B), Ro52 is not an integral component of the Y1 to Y5 RNPs. It is an interferon (IFN)-inducible member of the tripartite motif (TRIM) family bearing a RING motif that functions as an E3 ligase and ubiquitinates the transcription factor IFN regulatory factor 8.⁷

Anti-Ro/La autoantibodies are associated with sicca symptoms in Sjögren syndrome, SLE, PM/DM, and SSc. The prevalence of anti-Ro60 in primary Sjögren syndrome is 60% to 80%, whereas in SLE it is 10% to 50%.¹ Significant ethnic differences are seen in the prevalence (see Fig. 130.5). The prevalence of anti-La autoantibodies ranges from 10% to 20% in SLE and Sjögren syndrome (see Fig. 130.5). Anti-La autoantibodies are nearly always associated with anti-Ro60 or anti-Ro52, or both.

Fig. 130.4 (a) U1 snRNP. The particle contains proteins reactive with anti-Sm antibodies (B', B, D1, D2, D3, E, F, G), as well as anti-RNP antibodies (A, 70K, C), all associated with a single molecule of U1 small RNA. (b) Human Y1 ribonucleoprotein. The Ro60 protein is associated with a single molecule of human Y1 RNA (hY1). La (SS-B) antigen associates transiently with sequences located at the 3' end of the newly synthesized hY1 RNA. (c) Nucleosomes and chromatin. DNA is looped around the core histone (H2A/H2B)₂, H3, and H4 octamers to form nucleosomes with the appearance of beads on a string. Histone H1 is associated with linker DNA sequences. More complex folding and the association of additional nonhistone proteins result in the formation of chromatin fibers.

Anti-Ro60, anti-Ro52, and anti-La autoantibodies are associated with neonatal cardiac conduction abnormalities, including congenital complete heart block.⁸ These autoantibodies pose a risk to the fetus during pregnancy; although the risk for conduction abnormalities is low, screening should be performed in pregnant women with systemic autoimmune diseases, as well as in asymptomatic women with a previous pregnancy complicated by fetal heart block. IgG anti-Ro/La antibodies cross the placenta and damage the conduction system by binding to autoantigens from apoptotic cells, followed by an Fc receptor-mediated inflammatory response consisting of production of tumor necrosis factor- α (TNF- α) and fibrosis.⁸ Anti-Ro60 and anti-La autoantibodies are also associated with subacute cutaneous lupus, a photosensitive skin rash. Subacute cutaneous lupus induced by hydrochlorothiazide, terbinafine, and other drugs is likewise associated with anti-Ro. Transplacental passage of anti-Ro/La antibodies can cause a similar, but transient rash in neonates (neonatal lupus syndrome).⁹

DNA, nucleosomes, and chromatin

Chromatin consists of double-stranded DNA (dsDNA) with its associated histones and nonhistone proteins. The DNA is wound around a core histone octamer consisting of two molecules each of H2A/H2B, H3, and H4.¹ A single octamer with 145 base pairs of DNA wound around it is called a nucleosome (see Fig. 130.4c). Anti-DNA, antinucleosome, and antichromatin autoantibodies exhibit a homogeneous pattern of staining in the fluorescent ANA assay (see Fig. 130.1c).

Autoantibodies against chromatin and nucleosomes are diverse. The LE phenomenon is caused by a subset of these antibodies. The most important target antigen in SLE appears to be the H2A/H2B/DNA complex, although antibodies against this structure are not disease specific. Autoantibodies to chromatin, nucleosomes, and single-stranded DNA (ssDNA) are also found in SSc, drug-induced lupus, and SLE. In procainamide-induced lupus,

anti-H2A/H2B/DNA antibodies may be found a year or more before the onset of symptoms and, at the time of diagnosis, are present in 84% of patients. They disappear after cessation of use of the drug and, unlike anti-dsDNA antibodies, are not associated with nephritis.

Anti-dsDNA antibodies are 95% specific for SLE if appropriate assays are used.¹ At some time during the disease course, approximately 70% of SLE patients have anti-dsDNA antibodies, and at any particular point in time, about half are positive (see Fig. 130.5). The glomerular immune deposits in some patients with lupus nephritis are enriched in anti-dsDNA, thus suggesting that anti-DNA immune complexes are pathogenic.¹ However, not all patients with anti-DNA antibodies develop nephritis. Immune complexes become trapped in the glomerular basement membrane (GBM) during filtration or form *in situ* when nucleosomes are deposited in the GBM and later bound by autoantibodies. Cross-reactivity with endogenous glomerular antigens may be important for nephritogenicity.¹⁰ Mammalian DNA interacts with Toll-like receptor 9 (TLR9), which raises the possibility that immunostimulatory DNA in immune complexes could play a role in renal inflammation (see later). In mice, glomerular inflammation is dependent on IgG binding to stimulatory Fc receptors because Fc γ RI/III-deficient mice have immune deposits but not renal damage.¹¹

Anti-DNA measurements may be useful for monitoring disease activity. Anti-DNA and complement (C3, C4) levels sometimes vary reciprocally over time, although the clinical usefulness of this observation is somewhat controversial.¹² Assays for anti-DNA, such as radioimmunoassay (the Farr assay), *Crithidia luciliae* kinetoplast staining assay, and ELISA, must distinguish between anti-ssDNA and anti-dsDNA antibodies because only the latter are useful for monitoring disease activity. Specificity for dsDNA is ensured by removing ssDNA via S1 nuclease treatment or by using circular dsDNA as in the *Crithidia* assay. The *C. luciliae* kinetoplast is a closed circular DNA molecule packaged in histones that can be used to detect anti-dsDNA antibodies by immunofluorescence. High-affinity anti-dsDNA

TABLE 130.1
Examples of diagnostically important autoantibodies

Disease	Autoantibody	Clinical associations
Systemic lupus erythematosus (SLE)	dsDNA	Highly specific for SLE with renal disease and increased IFN
	Sm	Highly specific for SLE with renal disease and increased IFN
	Ribosomal P0, P1, P2	Highly specific for SLE, increased risk for neuropsychiatric disease
	RNA helicase A	Highly specific for SLE, marker for early lupus
	PCNA	Not specific for SLE; increased risk for thrombosis, fetal loss, and neuropsychiatric disease
Mixed connective tissue disease (MCTD)	Proteins, such as β_2 -glycoprotein I, bound to anionic phospholipids	Not specific for SLE; increased risk for thrombosis, fetal loss, and neuropsychiatric disease
Mixed connective tissue disease (MCTD)	RNP	Highly sensitive for MCTD but not specific
Systemic sclerosis (SSc)	Scl-70 (topoisomerase I)	Highly specific for SSc with a poor prognosis
	Fibrillarin	Highly specific for SSc
	RNA polymerase I/III	Highly specific for SSc with a poor prognosis
	To/Th	Highly specific for SSc
CREST syndrome	Centromere	
Polymyositis	tRNA synthetases: histidyl (Jo-1), threonyl, alanyl, isoleucyl, glycyl, leucyl, aspartyl, and others	Highly specific for myositis with "antisynthetase syndrome" (myositis, interstitial lung disease, inflammatory arthritis, Raynaud phenomenon, mechanic's hands)
	Signal recognition particle (SRP)	Highly specific for myositis with a poor prognosis
Sjögren syndrome (SS)	Ro60 (SS-A)	Sicca syndrome in primary or secondary SS, neonatal lupus/heart block
	Ro52	Sicca syndrome in primary or secondary SS, neonatal lupus/heart block
	La (SS-B)	Sicca syndrome in primary or secondary SS, neonatal lupus/heart block
Rheumatoid arthritis (RA)	Cyclic citrullinated peptide	Highly specific for RA

CREST, calcinosis; Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia; dsDNA, double-stranded DNA; IFN, interferon; PCNA, proliferating cell nuclear antigen.

TABLE 130.2
Nucleic acid components of some major lupus autoantigens

Autoantibody	Autoantigen	Associated nucleic acid	Innate immune receptor
Anti-Sm	U1, U2, U4/U6, and U5 snRNPs	U1, U2, U4/U6, and U5 RNA	TLR7, (TLR3)*
Anti-RNP	U1 snRNP	U1 RNA	TLR7, (TLR3)*
Anti-Ro60 (SS-A)	Ro60 (transiently associated with La)	hY1, hY3, hY4, and hY5 RNA	TLR7
Anti-Su	Argonaute 2	MicroRNA	TLR7
Jo-1 and others	tRNA synthetases	tRNA ^{his} and others	?†
Anti-P0, P1, P2	Ribosomal P proteins	Ribosomal RNA	?
Anti-dsDNA	Nucleosomes	dsDNA	TLR9
Anti-chromatin	Nucleosomes	dsDNA	TLR9
Anti-PCNA	DNA polymerase δ	dsDNA	TLR9
Anti-Ku	DNA-binding subunit of DNA-dependent protein kinase	dsDNA	TLR9

*Ultraviolet radiation-damaged U1 RNA interacts with Toll-like receptor 3 (TLR3).
†Known to be immunostimulatory but the receptor has not been identified.
snRNP, small nuclear ribonucleoprotein.

antibodies detected by the Farr assay may be the most predictive of disease activity.¹² Though controversial, some would institute corticosteroid therapy when Farr assay activity increases.¹³

Ribosomal P0, P1, and P2 autoantigens

Autoantibodies against ribosomal P0, P1, and P2 antigens recognize proteins of 38, 19, and 17 kDa, respectively (see Fig. 130.3b), which are components of the large (60S) ribosomal subunit. They bind primarily to a conserved

epitope on the C-terminal 22 amino acids of all three proteins¹⁴ and form a pentamer with the structure P0-(P1/P2)₂, which is part of the ribosomal guanosine triphosphatase center and mediates ribosomal interactions with elongation factors.

Anti-P0/P1/P2 autoantibodies are highly specific for SLE and have been linked with neuropsychiatric manifestations.¹⁵ The prevalence of anti-P in our cohort is less than 5% (see Fig. 130.5). Although the association of anti-P antibodies with neuropsychiatric lupus is somewhat controversial, a multicenter study did confirm an association between anti-P and neuropsychiatric lupus, but its sensitivity was low.¹⁶ Thus, anti-P antibodies are a good marker for SLE but only weakly predict neuropsychiatric involvement (see Table 130.1). Anti-P autoantibodies can be detected readily by immunoprecipitation (see Fig. 130.3b) but are generally detected by ELISA using a synthetic peptide containing the dominant C-terminal epitope.

PCNA, RNA helicase A, Ku, and Su antigens

PCNA is a 36-kDa auxiliary factor for DNA polymerase δ . Autoantibodies are found in 1% to 5% of SLE sera and are fairly disease specific.¹⁷ They are detected most reliably by immunoprecipitation (see Fig. 130.3b). The antigen is loosely associated with the nucleus in resting (G0) cells. Anti-PCNA antibodies stain the nuclei of proliferating but not resting cells, thereby resulting in variable fluorescence intensity (see Fig. 130.1c). Because of the low prevalence of anti-PCNA (see Fig. 130.5), it is of limited usefulness clinically.

Autoantibodies to RNA helicase A are produced primarily by nonblack SLE patients and are highly disease specific.¹⁴ Unlike anti-Sm, they appear early in disease and then disappear. Their prevalence is 3% to 7.5% in SLE. The antigen is an abundant 140-kDa member of the DExD/H box family (see Fig. 130.3b), which is thought to be a transcriptional coactivator bridging transcription factors and cofactors.

The Ku antigen is a heterodimer consisting of 70- and 80-kDa subunits that bind the termini of dsDNA breaks. It is the DNA-binding subunit of a DNA-dependent protein kinase (DNA-PK).¹⁸ Ku-DNA-PK plays a critical role in the nonhomologous end-joining reaction during immunoglobulin V(D)J recombination and class switch recombination. Deficiency of Ku70, Ku80, or the DNA-PK catalytic subunit causes severe combined immunodeficiency (because of an inability to rearrange immunoglobulin and T-cell receptor gene segments) and defective repair of radiation-induced DNA

Fig. 130.5 Sera from 1281 patients meeting the American College of Rheumatology criteria for the classification of lupus were tested for lupus-associated autoantibodies either by immunoprecipitation (anti-Sm, anti-RNP, anti-Ro60, anti-La, anti-Su, anti-ribosomal P, anti-PCNA, anti-Ku) or by enzyme-linked immunosorbent assay (anti-dsDNA). The percentage of positive sera is plotted by ethnicity.

damage. Autoantibodies against Ku are found in about 10% of black lupus patients but are rare in whites (see Fig. 130.5). Besides SLE, they can be detected by ELISA or immunoprecipitation in patients with PM/DM, SSc, and PM-SSc overlap syndrome (see Fig. 130.3b).

Anti-Su autoantibodies immunoprecipitate several proteins, including the 100-kDa human Argonaute (Ago) protein hAgo2, a catalytic enzyme in the RNAi pathway.¹⁹ Many of the sera also recognize other components of the pathway, such as hAgo 1, 3, and 4 and Dicer. The prevalence of these antibodies is 10% to 20% in SLE (see Fig. 130.5), but anti-Su antibodies also are seen in SSc, overlap syndromes, and other diseases.

Phospholipid-dependent antigens

The initial evidence for “antiphospholipid” autoantibodies came from the high frequency of false-positive syphilis test results in patients with SLE. The Venereal Disease Research Laboratory or rapid plasma reagin test is positive, but confirmatory testing with the antitreponemal antigen test is negative. The basis for these false-positive reactions is the presence of a phospholipid (cardiolipin) in the antigen mixture. “Anticardiolipin” antibodies do not actually bind the anionic phospholipid but instead recognize serum proteins, most commonly β_2 -glycoprotein I, that bind cardiolipin.²⁰ Autoantibodies against other anionic phospholipid-binding proteins, such as protein S and protein C, are less common. A subset of antiphospholipid antibodies called “lupus anticoagulants” are detected because they prolong *in-vitro* phospholipid-dependent coagulation tests, such as the partial thromboplastin time or the dilute Russell viper venom time. Though termed “anticoagulants,” they are procoagulant and therefore associated with an increased risk for thrombosis and fetal loss.²⁰ Antiphospholipid autoantibodies are found in 20% to 40% of SLE patients, less than half of whom have “antiphospholipid syndrome,” defined as vascular (venous or arterial) thrombosis or pregnancy morbidity with either anticardiolipin antibodies or a lupus anticoagulant. Antiphospholipid autoantibody syndrome is discussed in Chapter 139.

Cell membrane antigens

Patients with SLE can produce autoantibodies against the membrane antigens of erythrocytes, platelets, neurons, endothelial cells, lymphocytes, and neutrophils. Most common are antierythrocyte autoantibodies, which

are demonstrable with the direct antiglobulin (Coombs) test, in which antibodies bound to the patient's erythrocytes are detected by adding antihuman immunoglobulin antibodies to washed erythrocytes and observing for agglutination of the red cells. In some cases, these antibodies cause Fc receptor-mediated destruction of erythrocytes in the reticuloendothelial system of the spleen and liver. Warm autoantibodies (typically IgG), which bind optimally at 35° C to 40° C, are the most characteristic of SLE. They are usually directed against Rh antigens, although in some cases immunoglobulin eluates from lupus erythrocytes contain anticardiolipin antibodies. If removal of IgG-coated erythrocytes by the reticuloendothelial system exceeds the ability of bone marrow to replace them, anemia ensues. Although 10% to 50% of SLE patients are direct Coombs positive, most do not have autoimmune hemolytic anemia.

Antiplatelet autoantibodies cause idiopathic thrombocytopenic purpura (ITP), a disorder of platelet consumption that may exist by itself or in conjunction with SLE. The disease in SLE patients is indistinguishable from “primary” ITP. The main target appears to be the glycoprotein IIb/IIIa (CD41/CD61) complex. Unfortunately, laboratory tests for antiplatelet antibodies are unreliable, complex, and not widely available. Matters are complicated further by the fact that preformed DNA/anti-DNA immune complexes, as well as anticardiolipin antibodies, can bind to platelets.

Autoantibodies against lymphocytes may cause lymphopenia in SLE. A variety of antigenic targets have been identified, including isoforms of CD45. Antineuronal antibodies have been identified in some SLE patients, and anti-DNA antibodies cross-reactive with the *N*-methyl-D-aspartate receptor cross the blood-brain barrier in humans and can cause neurologic disease in mouse models.²¹ However, their association with the neuropsychiatric manifestations of lupus remains somewhat controversial.¹⁶

AUTOANTIBODIES AS THE INITIAL MANIFESTATION OF AUTOIMMUNITY

Autoantibodies can play a direct role in disease pathogenesis, as in the transplacental transfer of anti-Ro/La autoantibodies in neonatal lupus and fetal heart block, autoimmune hemolytic anemia and thrombocytopenia, and antiphospholipid syndrome. It is puzzling, however, why only SLE patients produce certain autoantibodies that recognize intracellular antigens normally sequestered from the immune system. These disease-specific

autoantibodies can be the initial manifestation of disease and may appear months or years before the onset of symptoms. Anti-Ro/La, anti-Sm/RNP, anti-DNA, and antiphospholipid antibodies may appear long before the onset of SLE.²² The development of specific autoantibodies before the onset of disease is not restricted to SLE inasmuch as the same phenomenon is seen in biliary cirrhosis (antimitochondrial), limited (anticentromere) and diffuse (anti-Scl70) scleroderma, PM (anti-tRNA synthetase), and RA (rheumatoid factor and anti-citrullinated peptide antibodies).

MECHANISMS OF AUTOANTIBODY PRODUCTION IN LUPUS

Maintenance of self-tolerance

Mechanisms of self-tolerance are complex and their discussion is beyond the scope of this chapter; only a summary is provided here (see reviews for a complete discussion^{23,24}). Self-tolerance is achieved at multiple levels, both central and peripheral. Lymphocytes that strongly react with ubiquitous self-antigens are generally deleted centrally (before they exit the primary lymphoid organs), whereas autoreactive lymphocytes with lower affinity for self or reactive with antigens not found in the primary lymphoid organs are censored peripherally. Peripheral tolerance is maintained by deletion, anergy, and suppression, as well as by “ignorance,” in which autoreactive lymphocytes exit the primary lymphoid organs, but do not receive a strong enough activation signal. Lymphocyte activation requires two signals, one delivered by the antigen receptor (T-cell antigen receptor or surface immunoglobulin) and a “co-stimulatory” signal. In the absence of a co-stimulatory signal, engagement of the antigen receptor leads to unresponsiveness (anergy). Dendritic cells, the most potent antigen-presenting cells, can either initiate T-cell activation or promote peripheral tolerance, depending on their maturation state: antigen presentation by immature dendritic cells is tolerogenic, whereas presentation by mature dendritic cells is stimulatory. “Ignorance” arises when self-antigens are expressed at levels insufficient to provide a strong signal through the antigen receptor. For instance, self-peptides processed inefficiently by dendritic cells can neither stimulate immunity nor induce tolerance. However, if the same peptides are produced in larger quantity because of abnormal processing, they can activate autoreactive T cells and promote autoantibody production.

Resting B cells do not secrete immunoglobulin until they differentiate into plasma cells. Thus, autoreactive B cells can exist without detectable levels of serum autoantibodies, as shown in transgenic mouse models.²³ To activate autoantibody production, B cells generally need to encounter antigen and receive a second signal from an activated helper T cell. However, T-cell-independent antigens, such as pneumococcal polysaccharide, that carry repetitive epitopes can activate B cells by extensively cross-linking immunoglobulin receptors on their surface. Moreover, though controversial, TLR signaling may drive post-germinal center memory B cells into plasma cell development, thereby potentially maintaining long-term autoantibody production.²⁵

Finally, regulatory T cells (Tregs) are involved in peripheral tolerance. Although several Treg subsets exist, the CD4+CD25+FoxP3+ subset has received considerable attention recently as a regulator of autoimmunity.²⁴ A genetic defect in the transcription factor Foxp3, which controls Treg function, causes IPEX syndrome (immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome), in which organ-specific autoimmune diseases such as type 1 diabetes and autoimmune thyroiditis develop. However, for unclear reasons, lupus or other systemic autoimmune diseases do not develop in these individuals.

Chronic interferon overproduction in lupus

IFNs, which are cytokines with antiviral and antiproliferative effects, as well as effects on immune effector cells, are likely to be involved in the pathogenesis of SLE. They are classified as type I and type II.¹ IFN- γ is the sole type II IFN. IFN-I, which includes multiple IFN- α species, IFN- β , and others, is produced by leukocytes and fibroblasts and at high levels by plasmacytoid dendritic cells (pDCs). They all signal via the IFN-I receptor (IFNAR). Binding of IFN-I to IFNAR increases the expression of a group of IFN-stimulated genes (ISGs) regulated by the binding of STAT1 and other transcription factors to a cis-acting consensus sequence termed the *interferon-stimulated response element* (ISRE). This sequence is found in the promoters of all IFN-I-inducible genes. ISGs play a key role in the antiviral response, signal transduction, and apoptosis. Although as many as 100 genes are regulated by IFN-I, the subset involved in antiviral responses is of special interest with regard to SLE because expression of more than 20 of these genes (“IFN

signature”) is increased in peripheral blood mononuclear cells from SLE patients.^{26,27} Elevated IFN-I expression is associated with severe disease, renal involvement, and autoantibodies against dsDNA and RNA-associated antigens such as Sm, nRNP, SSA/Ro, and SSB/La.²⁸

IFN- α treatment of hepatitis C infection and neoplastic diseases can induce ANAs (in up to 22% of patients), anti-dsDNA antibodies, and SLE.^{25,29} Also, individuals with a partial trisomy of chromosome 9 involving the IFN-I gene cluster exhibit chronically elevated IFN-I and develop anti-RNP and anti-Ro60 autoantibodies.³⁰ IFN-I also plays a pathogenic role in murine lupus. Lupus in (NZB $\times$ NZW)F1 mice is accelerated by IFN- α ,³¹ and experimental lupus induced by 2,6,10,14-tetramethylpentadecane (pristane) is associated with the IFN signature and requires IFNAR signaling.³²

The causes of IFN-I dysregulation in SLE are being investigated. Both endosomal and cytoplasmic signaling pathways are responsible for IFN-I production in response to pathogen-associated molecular patterns.³³ TLR7 and TLR8 recognize viral ssRNA, and TLR9 recognizes unmethylated CpG DNA, generally of microbial origin. However, they can also recognize endogenous nucleic acids.^{34,35} TLR7, TLR8, and TLR9 stimulate IFN-I secretion through a signaling pathway that uses the adaptor protein MyD88.³³ In contrast, TLR3 (an endosomal receptor for viral dsRNA) uses a signaling pathway involving the adapter protein TRIF.³³ Foreign nucleic acids in the cytoplasm are also recognized by a variety of innate immune system receptors, including cytoplasmic RNA (e.g., RIG-I) and DNA (e.g., DDX41).³³

The production of anti-Sm/RNP and anti-DNA autoantibodies in pristane-induced lupus requires TLR7, MyD88, and the transcription factors IRF5 and IRF7, but it is independent of other pathways.^{32,36} Lupus in male BXSB mice results from duplication of the TLR7 gene, which enhances TLR7-mediated IFN production.^{36,37} Furthermore, both TLR7 and TLR9 have been implicated in autoantibody production in MRL mice.³⁸ Dysregulated IFN-I production stimulated by endogenous nucleic acids can be involved in the pathogenesis of lupus autoantibodies. Further supporting this model, a subset of patients treated with TNF- α inhibitors develop ANAs, anti-dsDNA antibodies, and even SLE.³⁹ Because TNF- α can downregulate IFN-I production,⁴⁰ these drugs may promote lupus by increasing IFN-I levels.

Endogenous TLR7 and TLR9 ligands

Although TLR9 in late endosomes or lysosomes recognizes the unmethylated CpG motifs common in viral or bacterial DNA, endogenous DNA also contains unmethylated CpG sequences capable of engaging TLR9 but does not cause immunostimulation because it fails to reach late endosomes.⁴¹ However, if endogenous DNA is delivered aberrantly to late endosomes as a result of complex formation with the antimicrobial peptide LL37, it can engage TLR9.⁴² Similarly, the U1 and Y RNA components of Sm/RNP and Ro60 autoantigens, respectively, can reach late endosomes and are endogenous ligands for TLR7.⁴³ Interestingly, the interaction of ultraviolet radiation-damaged U1 RNA with endosomal TLR3 is involved in the pathogenesis of sunburn,⁴⁴ although it is not yet known whether U1 RNA–TLR3 interactions play a role in the pathogenesis of photosensitive lupus rash. Endogenous TLR ligands can gain entry to late endosomes by forming immune complexes or as a result of abnormal processing by antigen-presenting cells.

Nucleic acid-containing immune complexes

Binding of immunoglobulin to nucleic acid-containing autoantigens can inhibit the endosomal degradation of autologous DNA or RNA and promote interactions with TLR7/8 or TLR9. For instance, pDCs express Fc γ RIIa (CD32) and can internalize DNA-containing immune complexes; the DNA is released and engages endosomal TLR9, which results in IFN-I production.³⁴ Likewise, the interaction of snRNPs with immunoglobulin on the surface of anti-Sm/RNP B cells promotes B-cell activation via TLR7 signaling.⁴⁵

Aberrant processing of endogenous TLR ligands

Programmed cell death (apoptosis) generates cellular debris that is cleared by phagocytes. Generally, this process is noninflammatory, whereas necrotic cells are proinflammatory.⁴⁶ Defects in the noninflammatory clearance of cellular debris are associated with autoimmunity. C1q is involved in apoptotic cell clearance, and lupus develops in both patients and mice deficient in C1q. Likewise, autoimmunity develops in mice deficient in serum amyloid P or other molecules that help clear apoptotic cells (Mer, MFG-E8, and CD31). Deficiency of CD14 or mannose-binding lectin, both of which promote the clearance of apoptotic cells, is not associated with autoimmunity,⁴⁶ thus suggesting that defects in the clearance of apoptotic cells do not, by themselves, lead to autoimmunity.

Abnormal intracellular processing of apoptotic cells may promote autoimmunity by allowing endogenous nucleic acids to interact with TLR7/9 within the acidic endosomal compartments. Lysosomes contain RNases and DNases that cleave the nucleic acid components of apoptotic cells. Mice deficient in DNase II, a lysosomal deoxyribonuclease that degrades DNA in apoptotic cells, die *in utero* as a result of IFN- α overproduction.⁴⁷ Conditional knockouts of DNase II develop an inflammatory arthritis resembling RA and low levels of autoantibodies, including anti-DNA.⁴⁸ Mutations of the 3' repair exonuclease *Trex1*, which increase cytoplasmic ssDNA levels and lead to high levels of IFN- α production and a characteristic rash (chilblain lupus), are found at increased frequency in SLE patients.⁴⁹

Defective handling of misfolded RNA is also associated with autoimmunity. A lupus-like syndrome with autoantibodies against nucleosomes and ribosomes plus glomerulonephritis develops in Ro60 knockout mice.⁶ In summary, enhanced delivery of endogenous TLR ligands to late endosomes as a result of immune complex formation, interactions with the antigen receptors of autoreactive (e.g., anti-Sm/RNP) B cells, abnormal processing by phagocytes, or overproduction of the ligands can promote inflammation and autoantibody production.

Characteristics of lupus autoantigens

Although the cell nucleus contains thousands of proteins, few become autoantigens in SLE (see Table 130.1 and Fig. 130.3b). Most of the major autoantigens consist of multiple proteins bound to nucleic acid. The fact that these autoantigens carry immunostimulatory RNA or DNA ("endogenous adjuvants") that can engage endosomal TLRs may help explain why they are autoantigens (see Table 130.2). Autoantigen structure also explains the existence of "linked sets" of interrelated specificities, such as the strong association of anti-Sm, anti-RNP, and anti-U1 RNA autoantibodies. Immune responses to multicomponent autoantigens are analogous to responses to viral particles in which T cells specific for one component of the virion can help B cells producing antibodies against the other components.¹ Thus, the structure of lupus autoantigens may be relevant both to the breaking of tolerance (because of the presence of immunostimulatory nucleic acids) and to the diversity of autoantibodies produced (because T cells responsive to one component can drive B cells specific for other components of the same complex to become plasma cells).

Pathogenesis of lupus

■ JOSÉ C. CRISPÍN ■ GEORGE C. TSOKOS

- Genetic predisposition is a major determinant of disease in patients with systemic lupus erythematosus (SLE).
- Apoptotic debris is a source of autoantigens in SLE.
- Dendritic cells present autoantigens to T cells and produce proinflammatory cytokines (e.g., interleukin-6, interferon- α).
- B cells produce autoantibodies that mediate tissue injury by numerous mechanisms.
- Abnormal T-cell signaling and gene expression lower the activation threshold of T cells and facilitate the production of proinflammatory cytokines.
- Local regulatory factors play a role in determining organ susceptibility to disease.

A chronic systemic inflammatory response manifested by the presence of a vast array of autoantibodies and gross alterations in T-cell function develops in patients with systemic lupus erythematosus (SLE). The clinical manifestations and organ damage are caused by a self-aimed immune response triggered by unknown factors that is reluctant to end. SLE is considered an autoimmune disease, and immunosuppressive agents represent the mainstay of its treatment.

The pathologic immune response observed in patients with SLE entails the complexity and features of a physiologic protective immune response. Hence, a description of its pathogenesis must take into account myriad elements that act in concert in any given patient to shape an immune system prone to being triggered by factors commonly innocuous, that erroneously directs an organ-damaging response against ubiquitous self-components, and that avoids regulation by the numerous layers of control that normally limit the scale and extent of immune activation.

SUSCEPTIBILITY AND TRIGGERING FACTORS

Strong evidence indicates that SLE has a major genetic component (see Chapter 127). It is characterized by familial aggregation, high concordance rates among twins, and different prevalence and severity between ethnic groups.¹ Several genes that encode proteins involved in the immune response have been associated with SLE. Most risk-associated polymorphisms are found in noncoding DNA regions, and their functional effects remain to be defined. However, rather than representing defect-causing mutations, their presence is predicted to only modulate the function of the associated gene product and perhaps facilitate immune responses to inflammatory stimuli (e.g., by lowering the activation threshold of cells or increasing their inflammatory properties). As a result, most lupus-associated polymorphisms convey a small risk for the development of lupus, and disease probably develops only in individuals who harbor a combination of numerous susceptibility alleles. This concept explains how the accumulation of genes conferring low risk can determine susceptibility and can also account for the observed differences in clinical behavior and severity of disease in patients with lupus. Different combinations of susceptibility alleles will generate different clinical phenotypes.

Female sex and hormones are the second major factor predisposing to the development of SLE. Studies performed in murine models of lupus have shown that estrogens promote autoimmune pathology whereas androgens protect against its development.² Estrogens increase the production of

B-cell-activating factor and synergize the effects of type I interferons (IFNs) on B cells.³ Estradiol and prolactin affect the negative selection process of B cells, and mice treated with these hormones have altered B-cell repertoires and an increased tendency for the development of autoimmune disease.⁴

The current paradigm assumes that the combined presence of several predisposing alleles tilts the balance of the immune system toward a behavior that favors self-reactivity over tolerance; female hormones lean the balance further. Tolerance is probably broken during immune activation in response to environmental factors (e.g., infections; [Table 131.1](#)).⁵⁻⁹ Cellular damage produced by infectious or noninfectious stimuli (e.g., ultraviolet light) increases the exposure of the immune system to self-antigens. However, a breach in tolerance must override strong regulatory mechanisms and probably occurs gradually; it is induced by multiple events, as suggested by the fact that autoantibodies accumulate slowly in patients with SLE years before clinical manifestations.¹⁰ It is important to consider that the immune system changes constantly over the years because of adaptation to the challenges that it encounters. T cells and B cells that become activated increase their numbers, and specific memory cells able to mount better responses on reencounter with the activating agent are created. Hence, the T- and B-cell memory repertoire varies according to the stimuli that have effectively activated the immune system. The immune system of a patient with lupus probably harbors a relatively large number of autoreactive T and B cells that drive a chronic self-aimed immune response. The products of this chronic response (e.g., activated T cells, autoantibodies) can cause target organ damage that results in clinical disease. Thus, in the context of genetic and hormonal susceptibility, encounters with environmental factors (i.e., agents that cause cell damage and activate the immune system) gradually mold a self-aimed chronic response able to instigate organ inflammation. It is important to conceptually separate the development of a chronic autoimmune response from the instigation of target organ pathology. The former is ubiquitous in patients with SLE and necessary for development of the disease. The latter, mainly responsible for clinical manifestations of the disease, is highly variable and regulated by different factors ([Fig. 131.1](#)).

The immune system of patients with SLE has been studied extensively, and defects have been described in most of its components. Each of these defects has been proposed to play a role in pathogenesis of the disease. In this chapter some of these alterations and how they might contribute to form an immune system capable of producing lupus are described.

ANTIGEN-PRESENTING CELLS AND CLEARANCE OF CELL DEBRIS

When monocytes migrate into tissues, they differentiate into two of the most important antigen-presenting cells (APCs), namely, myeloid dendritic cells (DCs) and macrophages. Although the differentiation process varies among tissues, it yields cells capable of acquiring particles and debris and, most importantly, able to detect the presence of danger signals derived from damaged or infected cells. In the absence of pathogen-associated signals, APCs present normal tissue-derived antigens to T cells in a noninflammatory fashion, which contributes to the maintenance of tolerance. In contrast, when APCs detect danger signals (e.g., uric acid released by necrotic cells, microbial products), they undergo a phenotypic transformation that allows them to become powerful T-cell activators.¹¹

Increased T-cell activation by DCs has been proposed as a pathogenic mechanism in lupus. However, because of their inherent plasticity, DCs from patients with SLE have been difficult to characterize. Some reports claim that they express higher levels of co-stimulatory molecules and secrete increased amounts of proinflammatory cytokines (e.g., interleukin-6 [IL-6]); others indicate that when DCs are generated in a nonautoimmune

milieu, their phenotype and function are normal. The immune complexes present in sera from patients with SLE stimulate macrophage and DC activation through immunoglobulin receptors (FcRs).¹² Sera from patients with SLE can induce the differentiation of monocytes into DCs.¹³ Thus, evidence suggests that because of either intrinsic defects, a proinflammatory environment, or both, DCs from patients with SLE have increased T-cell stimulation capacity and altered tolerance-promoting functions (Fig. 131.2).

Plasmacytoid DCs represent a distinct type of APC. When activated during viral infections, they produce IFN- α . Nucleic acid-containing immune complexes can also stimulate them to produce large amounts of type I IFN, which could represent a powerful amplification mechanism since the peripheral blood mononuclear cells of pediatric patients with active lupus have a gene expression profile suggesting that they have been exposed to type I IFN.¹⁴

In normal conditions, the load of autoantigens generated by cell death is cleared by APCs without eliciting inflammation or an immune response.¹⁵ Alterations in this process might be important in the pathogenesis of SLE because a number of commonly targeted autoantigens (e.g., Ro) are exposed to the immune system during apoptosis¹⁶ and apoptosis of peripheral blood mononuclear cells and keratinocytes has been found to be increased in patients with lupus. Increased loads of apoptotic material can overcome the scavenging capacity of the system and induce antinuclear antibodies in otherwise healthy animals.¹⁷ Deficiency of the proteins involved in apoptotic

cell clearance (e.g., C1q) confers a high risk for the development of lupus. Thus, apoptotic cells are probably an important source of antigens in patients with SLE. As occurs with other pathogenic processes, abnormalities in the presentation of antigens derived from apoptotic cells can worsen once the disease is established. Autoantibodies opsonize apoptotic cells in which antigens normally hidden inside the cell nucleus have emerged to the surface in apoptotic blebs. Uptake of opsonized particles induces APC activation and leads to T-cell stimulation, which interferes with the process of tolerance induction normally associated with the presentation of apoptotic cells.¹⁸ In this way, autoantibodies contribute to amplification of the autoimmune pathology and to the breach in tolerance toward the ubiquitous intracellular self-antigens.

In summary, evidence suggests that APCs are involved in the pathogenesis of SLE by virtue of their capacity to uptake and present antigens derived from apoptotic and damaged cells to T cells. Abnormal presentation of self-antigens by intrinsically or ill-differentiated DCs probably plays a role in the initiation and amplification of the autoimmune response in patients with SLE (see Figs. 131.1 and 131.2).

B CELLS AND THE PRODUCTION OF AUTOANTIBODIES

B-cell hyperactivity together with promiscuous autoantibody production is one of the most common immune alterations observed in patients with SLE. Accordingly, the proliferation rate and antibody production are increased in B cells from lupus patients. Autoantibodies in patients with lupus are typically of high affinity and produced by cells that have undergone class switch recombination and somatic hypermutation.¹⁹ These characteristics indicate that T cells were involved in their production and have provided help to autoreactive B cells, mainly by surface-bound CD40L and cytokine production.²⁰

Although the autoantibody response in SLE is broad and directed against numerous specificities, several hallmark antigens are intranuclear complexes composed of nucleic acids and proteins. This might be important from a pathogenic point of view since B cells can be stimulated by DNA and RNA through Toll-like receptors.²¹ Evidence obtained from animal models of lupus suggests that the nucleic acids contained in immune complexes can deliver a second signal to the B cell, complementary to the signal conveyed by the Fc portion of the immunoglobulin.²² Nucleic acid-containing immune complexes might be able to stimulate B cells without the need for

TABLE 131.1
Environmental factors postulated to be lupus triggers

Proposed mechanism	Factors	References
Increased cell apoptosis	Ultraviolet light	5
Alteration of self-antigens (e.g., enzymatic cleavage, phosphorylation)	Ionizing radiation	6, 7
	Exposure to heavy metals	
	Drugs	
Molecular mimicry	Viral infections	8
DNA hypomethylation	Drugs (procainamide, hydralazine)	9
	Ultraviolet light	

Fig. 131.1 The interplay of genetic, hormonal, and environmental factors initiates an autoimmune response that becomes chronic. Autoantibodies form immune complexes with antigens derived from apoptotic debris. Nucleic acid-containing immune complexes promote the secretion of type I interferon from plasmacytoid dendritic cells (pDCs). These elements further stimulate the immune system and thereby contribute to perpetuation and amplification of the autoimmune response in a cyclic manner. At some point, the products of this immune response (e.g., activated T cells, immune complexes) initiate an inflammatory response in target organs. Local factors may facilitate (e.g., local secretion of proinflammatory cytokines) or hinder (e.g., production of kallikrein) the duration and extent of the local injury. Products derived from damaged tissue may contribute further to amplification of the underlying immune response.

Fig. 131.2 In healthy individuals, apoptotic cell debris is cleared by macrophages and dendritic cells and presented to T cells in a noninflammatory context. This process ensures that autoreactive T cells are inactivated (left). Low-affinity Fc receptors, a low density of complement receptors, and genetic or acquired deficiency of complement factors diminish the capacity of the immune system of patients with lupus to scavenge immune complexes and apoptotic cell debris. These factors, along with an increased load of apoptotic cells, overload the immune system with autoantigens. The increased load in a susceptible individual leads to the development of autoantibodies. These autoantibodies opsonize apoptotic cells, which favors an inflammatory manifestation. Additionally, they form immune complexes that stimulate antigen-presenting cells, thus creating a vicious circle. B, B cell; DC, dendritic cell; Mo, monocyte; pDC, plasmacytoid dendritic cell; T, T cell.

T-cell–derived help, thus providing an alternative pathogenic amplification pathway independent of T-cell help and regulation.

The autoantibodies present in sera from SLE patients have been shown to be pathogenic through different mechanisms. Autoantibodies form immune complexes that can be detected in sera from patients with lupus. When immune complexes are deposited in the renal glomeruli and blood vessels, they induce inflammation by activating complement and engaging the FcRs in neutrophils and other inflammatory cells.²³ A factor that contributes to the immune complex–mediated tissue damage in lupus patients is deficient clearance as a result of genetically determined expression of lower-affinity receptors for IgG and decreased levels of complement receptors on red blood cells.²⁴ Autoantibodies can also induce tissue damage by mechanisms different from immune complex deposition. In murine models, certain autoantibodies obtained from patients can bind to the placenta and ischemic intestine and trigger inflammatory responses through complement and neutrophil activation,^{25,26} which leads to fetal resorption and to ischemia-reperfusion–mediated tissue injury, respectively. Alternatively, autoantibodies can bind to surface receptors and alter cellular function. For instance, some anti-DNA antibodies cross-react with neuronal N-methyl-D-aspartate receptors and cause neuronal apoptosis,²⁷ whereas anti-T lymphocyte antibodies can significantly alter T-cell function and cytokine production by activating intracellular pathways that modify the activation of transcription factors.²⁸ In pregnant patients, specific autoantibodies (e.g., anti-Ro) may cross the placenta and cause cellular damage in the fetus.^{29,30} Finally, penetration of autoantibodies into living cells has been proposed to explain certain cellular changes elicited by their presence.³¹

Each B cell assembles the antibody that it will use as a B-cell receptor and secretes it as immunoglobulin by rearranging its germline DNA in a random fashion. This process allows the creation of a vast array of different specificities but entails the expression of autoreactive antibodies. In fact, a large fraction of immature B cells harbor self-reacting polyspecific antibodies.³² Most self-reactive B cells are eliminated at two checkpoints before reaching the stage of naive immunocompetent cells, the first one at the immature B-cell stage, previous to their egress from bone marrow, and a second one in secondary lymphoid organs, before their maturation into naive immunocompetent B cells. This process, which allows elimination or functional neutralization of autoreactive B cells, is deficient in patients with SLE.³³ Thus, more autoreactive B cells prone to be stimulated by self-antigens are present in patients with SLE. The cause of this defect is mostly unknown but probably related to genetic and hormonal factors.³⁴

B cells are located in secondary lymphoid organs (i.e., spleen, lymph nodes, Peyer patches), where they are exposed to antigens. When a B cell

recognizes an antigen through its surface immunoglobulin, it presents antigen-derived peptides to CD4+ T cells. Local inflammation, cytokines, and pathogen-derived molecules entice antigen presentation by increasing the expression of co-stimulatory molecules on the B-cell surface. If the CD4+ T cell is activated effectively, it delivers a positive signal to the B cell via CD40L and IL-21 that induces the formation of a germinal center. Germinal center B cells proliferate extensively and during the process develop random mutations in the DNA sequences that encode the antigen-binding site of the immunoglobulin. A progeny of B cells with modified immunoglobulin results. A selection process ensues in which only B cells able to recognize with high avidity the antigen that initiated the process survive. In this way the germinal center response increases the avidity of the humoral immune response. How autoreactive B cells produced during the germinal center response are purged and how this process occurs in patients with SLE are matters of intense research. Animal models suggest that the germinal center response is a fundamental element of the autoimmune response in lupus,^{35,36} but specific defects in this process have not been linked to the human disease.

In summary, B cells are central players in the autoimmune response in lupus. They produce high levels of autoreactive antibodies that mediate tissue injury. Furthermore, B cells are able to act as APCs by internalizing soluble antigens, presenting them to T cells, and thereby creating a loop that amplifies and perpetuates the chronic autoimmune response³⁷ (see Fig. 131.1).

T CELLS AND REGULATION OF THE IMMUNE RESPONSE

T cells are central elements of the immune response. They define its characteristics and control its magnitude and length by stimulating or suppressing the function of other cells through direct cellular contact and secretion of cytokines and chemokines. They also act as effector cells that induce apoptosis in cells altered by infection. The behavior and function of T cells are altered in patients with SLE.³⁸ They participate in the chronic autoimmune response of lupus patients by providing help to autoreactive B cells and failing to suppress the pathologic immune response. They infiltrate target organs, where they promote the local inflammatory response by producing cytokines (e.g., IL-17).

Profound molecular defects alter the activation process of T cells from lupus patients. When stimulated through the T-cell receptor (TCR), they exhibit an abnormally rapid and high surge in intracellular calcium levels

accompanied by increased phosphorylation of signaling proteins.³⁹ This is caused by alterations in the composition of proteins associated with the TCR. Normally, TCR signal transduction is initiated by the TCR-associated molecule CD3- ζ . However, in T cells from SLE patients, this molecule is expressed at low levels and in abnormal cellular compartments.^{40,41} Its place is taken by an analogous molecule not normally expressed in T cells (i.e., the γ chain of the FcR). This substitution affects the manner in which SLE T cells respond to antigens. The presence of the FcR γ chain favors an alternative transduction pathway associated with the heightened calcium response. This pathway relies on Syk, a tyrosine kinase that is overexpressed in T cells from lupus patients.⁴²

The molecules involved in T-cell signaling are not distributed randomly throughout the cell membrane. They are localized in cholesterol-rich zones that migrate toward the pole of the cell where antigens are being presented. These zones, known as lipid rafts, allow rapid clustering of the molecules required to transduce the signals initiated in the TCR. This spatial reorganization of signaling molecules to a localized part of the cell membrane facilitates T-cell activation. From the point of view of lipid rafts, T cells from patients with lupus are not normal. Their lipid rafts are preclustered as if the cells were activated. This morphology may indeed reflect a state of activation—by autoantigens or perhaps anti-T-cell antibodies—and results in faster and larger activation kinetics that lead (along with the substitution of CD3- ζ) to the abnormal response on TCR ligation observed in T cells from patients with lupus.⁴³

T-cell activation is a complex process in which several signals, including those initiated by the TCR, are integrated. Importantly, signaling is not uniformly increased in cells from patients with lupus. In fact, decreased activity of other signaling pathways, in particular, the mitogen-activated protein kinase pathway, has been described in lupus T cells. As a result, SLE-derived T cells have lower levels of c-fos, a component of the transcription factor AP-1. Thus, when a lupus T cell is stimulated by an antigen, molecular defects distort the signal and alter the magnitude and quality of the response. Since the expression of certain proteins is excessive and the production of others is deficient, T cells from patients with lupus seem to be overactive in certain functions and fail to respond in others. For instance, expression of CD40L, an extremely important molecule used by T cells to stimulate DC activation and antibody production by B cells, is abnormally increased in T cells from lupus patients, but IL-2 secretion is deficient.

Gene transcription is regulated by a complex multilayered process that includes DNA methylation and posttranslational modification of histones.⁴⁴ DNA methylation acts as a repressor of transcription, and interestingly, two drugs associated with the induction of drug-induced lupus, procainamide and hydralazine, induce DNA demethylation. Moreover, DNA has been shown to be hypomethylated in T cells from patients with lupus, and administration of demethylating drugs causes a lupuslike disease in mice.⁴⁵ Although the mechanisms that lead from DNA demethylation to autoimmunity are not well understood, T cells treated with agents that induce DNA hypomethylation have a decreased activation threshold. Furthermore, the expression of certain genes that are potentially relevant for lupus pathogenesis is augmented when DNA is hypomethylated (e.g., the adhesion molecule LFA-1 and the B-cell-activating molecule CD70). PP2A, one of the major serine/threonine phosphatases, is overexpressed in T cells from lupus patients. This overexpression may result, at least in part, from DNA hypomethylation.⁴⁶ The increased levels of PP2A also affect T-cell IL-2 production. PP2A dephosphorylates the transcription factor CREB, thus further diminishing IL-2 transcriptional activity.⁴⁷

T cells from lupus patients have a distorted pattern of gene expression that alters their function. One of the most obvious is the skewed production of several cytokines (Table 131.2). Since cytokines represent one of the most important means that T cells use to deliver signals, aberrant cytokine production implies faulty immune regulation. The IL-2 secretion defect has been associated with several T-cell abnormalities that not only determine autoimmune pathology but also impair the development of protective immune responses against pathogens. Decreased IL-2 and IFN- γ production has been linked to defects in cytotoxic responses against viruses and other pathogens.⁴⁸ This, along with the use of immunosuppressive drugs, has placed infection-related mortality near the top of the list of causes of mortality in patients with lupus. On the other hand, decreased IL-2 has been postulated to be involved in regulatory T-cell abnormalities. Moreover, activation-induced cell death, a mechanism that allows the contraction of expanded clones of activated lymphocytes at the end of an immune response, also depends on the presence of IL-2. IL-17 is a T-cell-derived potent proinflammatory cytokine. The frequency of T cells able to produce IL-17 is increased in patients with lupus. Moreover, IL-17-producing T cells have been observed in the kidneys of patients with lupus nephritis, thus suggesting a role for this cytokine in the amplification of renal inflammation.⁴⁹

TABLE 131.2
Role of cytokines in the pathogenesis of lupus

Cytokine	Defect	Mechanism
IL-2	Decreased T-cell production	Altered T-cell effector function Altered regulatory T-cell development
IL-6	Increased mononuclear cell production	B-cell stimulation Promotion of IL-17 differentiation (?)
IL-10	Increased mononuclear cell production	B-cell stimulation
IL-12	Decreased mononuclear cell production	Promotion of IL-17 differentiation (?)
IL-17	Increased T-cell production	Promotion of inflammation
IL-21	Increased T-cell production	B-cell stimulation
IL-23	Increased mononuclear cell production	Promotion of IL-17 differentiation
IFN- γ	Defective T-cell production	Altered T-cell effector function

IFN- γ , interferon- γ ; IL-2, interleukin-2.

EFFECTOR T-CELL DIFFERENTIATION FAVORS B-CELL STIMULATION AND SECRETION OF PROINFLAMMATORY CYTOKINES

Fig. 131.3 Increased production of interleukin-6 (IL-6) and IL-23 by antigen-presenting cells facilitates the development of a T-cell repertoire rich in interleukin-17 (IL-17)- and IL-21-producing T cells that promote inflammation and B-cell antibody production, respectively. These proinflammatory conditions, along with low secretion of IL-2, probably decrease the differentiation and function of regulatory T cells. Effector differentiation of CD8+ T cells is also impaired. As a result, diminished numbers of cytotoxic cells and augmented double negative (DN) T cells are produced. These alterations directly contribute to disease pathogenesis and at the same time diminish the pathogen-clearing efficiency of the immune system.

T cells acquire the capacity to produce IL-17 when antigen presentation occurs in the presence of transforming growth factor- β and inflammatory cytokines such as IL-6 or IL-21. Such functionally differentiated cells have been called type 17 helper T cells (Th17). IL-12, IL-4, and IFN- γ suppress Th17 differentiation. DCs from patients with lupus secrete higher amounts of IL-6 and lower amounts of IL-12. This combination, along with a paucity of IL-2 and IFN- γ , probably facilitates the priming of naive cells into the Th17 effector phenotype in the altered cytokine milieu characteristic of patients with lupus (Fig. 131.3).

Regulatory T cells limit the length and magnitude of immune responses. Patients with lupus have low numbers of regulatory T cells that exhibit decreased suppressive capacity.⁵⁰ Several factors may account for this. IL-2

is necessary for the development and maintenance of regulatory T cells. Its deficiency, along with the presence of inflammatory cytokines, might hamper regulation; on the other hand, activated T cells are probably resistant to suppression. CTLA-4, a molecule involved in regulatory T-cell function, has been linked to lupus in genetic studies, but no functional consequence of the associated polymorphism has been conclusively demonstrated. Thus, intrinsic defects or the altered cytokine milieu characteristic of patients with lupus might account for the regulatory T-cell defects.

Patients with lupus have increased amounts of double-negative (DN) T cells (i.e., T cells that lack CD4 and CD8) in peripheral blood. Although the reason for this expansion is not understood completely, it is probably driven by excessive T-cell stimulation. DN T cells can stimulate B-cell antibody production by secreting cytokines (e.g., IL-4, IL-10). Importantly, DN T cells produce a variety of proinflammatory cytokines, including IL-17, and are major components of cellular infiltrates in the kidneys of patients with lupus nephritis.⁵¹

The localization of immune cells throughout the body and their entry into tissues are tightly regulated by the expression of receptors on the surface of cells and endothelium. T cells from SLE patients exhibit an increased capacity to bind to receptors expressed by endothelial cells and to migrate in response to chemokines. This ability, conferred by enhanced CD44 expression, probably facilitates their migration into target organs, where they can induce tissue damage and amplify the inflammatory response by secreting cytokines and chemokines.⁵²

In summary, abnormal signal transduction and epigenetic deregulation lead to obvious alterations in T-cell phenotype and function that are manifested as a decreased activation threshold and increased inflammatory capacity. T-cell-dependent regulation of the immune system is thus skewed toward autoreactivity and inflammation, and T-cell effector functions are enhanced (see Fig. 131.3).

LOCAL FACTORS THAT CONTRIBUTE TO LUPUS PATHOGENESIS

The presence of the chronic autoimmune response observed in patients with SLE is a step needed for the development of target organ injury. However, other factors determine the pathogenicity that products of this response exert on target organs. Injection of immune complex-containing serum from patients with SLE caused glomerulonephritis only in mice that expressed IgG receptors (FcγRIIA) in neutrophils and lacked the integrin Mac-1. Glomerulonephritis did not develop in Mac-1-sufficient mice even though the amount of immune complex deposition in the renal glomeruli

was comparable to that observed in susceptible Mac-1-deficient mice.⁵³ An analogous phenomenon occurs in patients with SLE. Although most have immune complex deposition in the renal glomeruli and the dermoepidermal junction, local inflammation develops in only a fraction. Moreover, even though the deposits are chronic, the inflammation can be episodic. This indicates that the mere presence of chronic autoimmune disease is not sufficient to cause clinically relevant lupus.

Some of the molecules associated with lupus may contribute to the disease by increasing organ susceptibility to immune-mediated damage. Overexpression of the phosphatase PP2A in the T cells of an otherwise healthy mouse did not cause autoimmunity, but it did increase the renal damage with induced glomerulonephritis. This effect was explained by increased production of the proinflammatory cytokine IL-17.⁵⁴

The response of the target organ itself is an important determinant of the magnitude of injury instigated by the autoimmune response. Certain polymorphisms in kallikrein genes are associated with ameliorated glomerulonephritis in mice, and single nucleotide polymorphisms in the *KLK1* and *KLK3* genes are associated with nephritis in patients with SLE. This suggests that the amount of kallikrein produced on immune complex deposition regulates the intensity of the immune response and thus the extent of immune-mediated glomerular damage.⁵⁵ Calcium/calmodulin-dependent protein kinase type IV (CaMK4) is a serine/threonine kinase that can be activated by serum-derived factors.²⁸ In mice of the lupus-prone strain MRL/lpr, CaMK4 induces the proliferation of glomerular mesangial cells and promotes their production of IL-6,⁵⁶ thus suggesting that the response of glomerular mesangial cells to immune complex deposition and serum-derived factors can actually contribute to the amplification and perpetuation of renal disease in these mice.

CONCLUDING REMARKS

Lupus is the clinical manifestation of a series of gross alterations in immune function and regulation. These alterations gradually accumulate in individuals who harbor genetic and hormonal susceptibility factors when their immune system interacts with stimuli derived from the environment. The immune system of patients with lupus develops an autoimmune response directed against several widely expressed autoantigens that becomes chronic. Unknown factors trigger target organ damage when the products of the chronic autoimmune response produce inflammation in critical organs. Understanding the mechanisms that underlie both the breach in tolerance and the development of tissue injury will allow the development of better therapies that can alleviate this complex disease.

Drug-induced lupus

■ DIPAK R. PATEL ■ BRUCE C. RICHARDSON

- Drug-induced lupus (DIL) remains an underrecognized clinical entity.
- Most of the reported associations are case reports or case series and have not been examined carefully in epidemiologic studies.
- Some of the newer biologic and anticytokine therapies, including anti-tumor necrosis factor- α agents and interferon- α/β , appear to be associated with an increased incidence of DIL.
- Understanding the mechanisms behind DIL will probably provide important insight into the pathogenesis of autoimmunity.

HISTORICAL ASPECTS

Lupus develops when people with the appropriate predisposing genes are exposed to certain environmental factors, and drug-induced lupus (DIL) represents the clearest example of a defined environmental agent triggering lupus in genetically susceptible individuals. The first definite association between a drug and the onset of lupus was made in 1954 with the observation that a lupus-like illness developed in approximately 7% of hydralazine-treated patients.^{1,2} In the following decade, procainamide and anticonvulsants were added to the list of lupus-inducing drugs. With the advent of modern autoantibody testing, it became clear that many therapeutic agents are capable of inducing antinuclear antibodies (ANAs) in patients. Depending on the agent, clinical features resembling idiopathic lupus will develop in a variable proportion of these patients. More than 100 drugs have now been reported to cause DIL (Box 132.1), including a number of newer biologics.

EPIDEMIOLOGY

The annual incidence of DIL in the United States has been estimated to be 15,000 to 30,000 new cases per year. Approximately 30,000 to 50,000 patients are affected at any given time, which represents 6% to 12% of all lupus cases.³ The frequency of DIL is probably underreported because many cases are mild and self-limited once the offending drug is removed. The epidemiology of DIL reflects the population taking the particular lupus-inducing drug. For example, older men are more likely to take procainamide and hydralazine for cardiovascular disease, and younger women are more likely to take minocycline for acne. As expected, more cases of procainamide- and hydralazine-induced lupus occur in men and more cases of minocycline-induced lupus occur in women. However, DIL is two to four times more likely to develop in women who take hydralazine or procainamide than in their male counterparts. The reasons for this observation are unclear but may involve both hormonal and nonhormonal gender-associated factors. Little is known about racial susceptibility to DIL. Whites have been reported to be affected up to six times more frequently than blacks and to have more severe disease.⁴ However, this may simply represent demographic bias in the populations studied.

GUIDELINES FOR DEFINING DRUG-INDUCED LUPUS

No diagnostic criteria for DIL have been established, and many cases of DIL do not satisfy the American College of Rheumatology criteria for idiopathic

lupus. In addition, most reported associations are either case reports or case series with no epidemiologic or long-term clinical or laboratory studies to confirm a causal effect. Borchers and colleagues⁵ proposed criteria that include sufficient and continuous exposure to a drug, at least one symptom characteristic of lupus, no previous evidence of lupus or other autoimmune disease, and resolution of the disease within weeks or months after cessation of the suspected drug. A positive ANA is not required in this classification system, and the authors acknowledged that a negative ANA result should not rule out DIL when other laboratory test results support the diagnosis. Thus, clinicians should determine whether there is a temporal relationship between onset of the drug therapy and development of the clinical and serologic signs of lupus, as well as resolution of these clinical and laboratory signs after treatment with the drug is discontinued. Disease remission on discontinuation of a drug and recurrence with restarting the drug would confirm causality, and this has been reported for hydralazine,¹ procainamide,⁶ isoniazid,^{7,8} chlorpromazine,⁹ quinidine,¹⁰ and minocycline.¹¹

The diagnosis of DIL can be particularly difficult to make in patients with underlying systemic rheumatic diseases. Drug-induced rheumatic complaints may also be misinterpreted as an exacerbation of the underlying illness. The physician may then intensify the treatment regimen, thereby perpetuating the real problem. This could potentially happen, for example, with minocycline, sulfasalazine, or anti-tumor necrosis factor (TNF) agents in patients with rheumatoid arthritis.

CLINICAL FEATURES

It is not possible to distinguish DIL from idiopathic lupus by clinical features, although patients with DIL generally have a milder illness. Myalgia, fever, and serositis are more common in DIL. Arthralgia, but not frank arthritis or joint effusion, is also more common in DIL. In contrast, renal involvement, central nervous system disease, malar rash, discoid rash, photosensitivity, and oral ulcers occur less frequently in DIL.^{12,13} A positive “lupus band” test and Sweet syndrome have also been described in DIL, but these features are neither sensitive nor specific in differentiating DIL from idiopathic lupus.

In hydralazine-induced lupus, discoid rash and malar rash occur commonly, but leukopenia, neuropsychiatric symptoms, pericarditis, skin vasculitis, and renal involvement are less likely to develop than in idiopathic lupus. In procainamide-induced lupus, arthralgia, myalgia, constitutional symptoms, and serositis are the most common symptoms³ (Table 132.1). Pericarditis and rarely pericardial effusion or tamponade have been reported in DIL associated with procainamide,^{14,15} hydralazine,¹⁶ isoniazid,¹⁷ and sulfasalazine.¹⁸ Severe cases of DIL with hydralazine^{19,20} and procainamide treatment,²¹ as well as with quinidine,²² penicillamine,²³ and interferon (IFN)²⁴ treatment, have also been reported to involve immune complex glomerulonephritis. It is important to remember that the impaired renal function in these patients may also be due to other underlying medical conditions, such as hypertension or diabetes, or be due to medications such as nonsteroidal antiinflammatory drugs (NSAIDs). Minocycline-induced lupus is characterized by small-joint polyarthralgia and arthritis and diffuse myalgia. About half the patients affected have laboratory evidence of liver involvement and 20% have rash. Pleuropulmonary and hematologic involvement is uncommon, and the nervous system and kidneys are usually spared.^{25,26}

Several new clinical associations have been described in recent years. Although it will be impossible to consider every drug, a few are discussed in this chapter.

IFNs have antitumor, antiviral, and immunomodulating properties, and both IFN- α and IFN- β ²⁷⁻³¹ have been linked to the development of ANAs

BOX 132.1 DRUGS IMPLICATED IN DRUG-INDUCED LUPUS

Drugs with good evidence of association	Leuprolide acetate
Adalimumab	Levodopa
Carbamazepine	Levomeprazine
Chlorpromazine	Lithium carbonate
Etanercept	Lovastatin
Ethosuximide	Mephenytoin
Hydralazine	Mesalazine
Infliximab	Methimazole
Isoniazid	Methylsergide
Methyldopa	Methylthiouracil
Minocycline	Metrizamide
Penicillamine	Minoxidil
Phenytoin	Nalidixic acid
Procainamide	Nitrofurantoin
Quinidine	Nomifensine
Sulfasalazine	Omeprazole
	Oral contraceptives
	Olsalazine
Case reports	Oxyphenisatin
Acebutolol	Pantoprazole
Aminoglutethimide	Paraaminosalicylic acid
5-Aminosalicylic acid	Penicillin
Amiodarone	Perazine
Amoprofan	Perphenazine
Anthiomaline	Phenelzine
Atenolol	Phenopyrazone
Atorvastatin	Phenylbutazone
Benoxaprofen	Phenylethylacetylurea
L-Canavanine	Pindolol
Captopril	Practolol
Chlorprothixene	Prazosin
Cimetidine	Primidone
Cinnarizine	Promethazine
Clonidine	Propylthiouracil
Clozapine	Psoralen
COL-3	Pyrithiazine
Danazol	Pyrithioxine
Diclofenac	Quinine
1,2-Dimethyl-3-hydroxypyridine-4-1 (L1)	Rifamycin
Disopyramide	Sulfasalazine
Esomeprazole	Simvastatin
Estrogens	Spironolactone
Etanercept	Streptomycin
Flutamide	Sulindac
Fluvastatin	Sulfadimethoxine
Gold salts	Sulfamethoxypyridazine
Griseofulvin	Terbinafine
Guanoxan	Tetracycline
Hydrazine	Tetrazine
Ibuprofen	Thionamide
Infliximab	Thioridazine
Interferon (α, β)	Timolol eye drops
Interleukin-2	Tolazamide
Labetalol	Tolmetin
Lamotrigine	Trimethadione
Lansoprazole	Zafirlukast

and clinical lupus. In one study of 135 patients undergoing IFN treatment for carcinoid tumors, newly positive ANA developed in 14% of the patients and an autoimmune disorder developed in 19%, including 1 patient with lupus characterized by arthritis, leukopenia, and ANA and anti-double-stranded DNA (dsDNA) antibodies.^{32,33} IFN-α treatment induces ANAs in 18% to 72% of patients receiving it, but DIL develops in only 0.1% to 2.1%. Other have shown the frequency of IFN-induced lupus to be between 0.15% and 0.7%, and anti-dsDNA antibodies will develop in up to 8% of patients receiving long-term IFN therapy.²⁷ Treatment of lupus-prone mice with IFN worsens the disease.³⁴ In addition, lupus patients have elevated IFN levels that correlate with their ANA and anti-DNA antibody titers and disease activity.^{35,36}

Anti-TNF agents are now standard treatment of rheumatoid arthritis, spondyloarthritis, psoriasis, and inflammatory bowel disease. Rash is the

TABLE 132.1 Clinical features of procainamide and hydralazine-induced lupus

Clinical features	Procainamide-induced lupus (%)	Hydralazine-induced lupus (%)
Arthralgia	77	85
Myalgia	44	57
Fever	41	38
Rash	9	27
Adenopathy	8	14
Hepatomegaly	25	24
Splenomegaly	12	14
Pleuropulmonary	75	30
Pericarditis	16	5
Neuropsychiatric	1	4
Renal	<1	13

most common characteristic of lupus induced by anti-TNF agents.³⁷ A 2008 review identified an increased incidence of rash, anti-dsDNA antibodies, low complement levels, leukopenia, and thrombocytopenia in lupus induced by anti-TNF agents versus lupus induced by other drugs.³⁸ Fifty-six patients with DIL were identified, 36 of whom met the criteria for the diagnosis of idiopathic lupus. Of those 36 lupus cases, 21 were secondary to infliximab, 10 to etanercept, and 2 to adalimumab. Notably, the symptoms induced by one anti-TNF agent do not always persist when patients start other anti-TNF agents. Williams and Cohen³⁷ reported lupus secondary to etanercept in a 62-year-old woman with rheumatoid arthritis. It resolved with discontinuation of the medication and did not recur after golimumab was started for the 6-month period reported. In contrast, Subramanian and coauthors³⁹ reported 13 patients with inflammatory bowel disease in whom lupus induced by infliximab developed. Eight patients were switched to either certolizumab or adalimumab. Six patients remained asymptomatic, but DIL again developed in one patient each receiving certolizumab or adalimumab. A 2003 study reported on patients with Crohn disease who were treated with infliximab and monitored prospectively.^{39a} None of the patients had positive ANAs before starting treatment, but more than 56% were positive after 2 years of treatment. Of the patients who were studied further, approximately one third had anti-dsDNA antibodies. Notably, of the 125 patients, DIL developed in only 2 and autoimmune hemolytic anemia in 1. Anti-TNF agents frequently cause ANAs in patients receiving them, but rarely autoimmune diseases. Infliximab causes a positive ANA in 23% to 53% of patients, but DIL in 0.19%; adalimumab causes a positive ANA in 12.5% to 41.4%, but DIL in 0.41%; and etanercept causes a positive ANA in 11% to 48.8%, but DIL only 0.18% (reviewed in reference 40).

Proton pump inhibitors and statins are among the most commonly prescribed medications in the United States, and they are frequently used in rheumatology patients. A recent review of 117 subacute cutaneous lupus erythematosus cases identified 2 caused by lansoprazole, and there are also case reports involving omeprazole, esomeprazole, and pantoprazole.^{41,42} The first case reports of lupus induced by statins appeared in 1991, and there have been less than 20 reports overall.⁴³ In a recent case/noncase study in a French database of adverse drug reactions, 232 cases were classified as DIL.⁴⁴ Of these cases, statins were used in 17 (7.3%). In comparison, in more than 230,000 cases that were not DIL, statins were used in 4.7%. The odds ratio for the development of DIL with statin exposure was 1.67 (95% confidence interval, 1.02 to 1.74), and the odds ratio was greater than 1 with all statins except fluvastatin, for which no cases were recorded in that database.

Complementary and alternative medications

Herbal medications are becoming increasingly popular, and some have been linked to flares of lupus. Alfalfa sprouts were first linked to lupus in 1981, when autoimmune hemolytic anemia developed in a man after their ingestion.⁴⁵ Autoimmune hemolytic anemia, ANAs, anti-dsDNA antibodies, and low complement levels developed in macaques fed alfalfa sprouts. Furthermore, tablets containing L-canavanine, which is a constituent of alfalfa sprouts, reactivated a lupuslike syndrome in macaques in whom lupuslike features originally developed after eating alfalfa sprouts.^{46,47} L-Canavanine was later shown to decrease concanavalin A-induced suppressor T-cell

functions in cells from healthy controls and lupus patients, and this caused increased IgG and anti-dsDNA antibodies from stimulated B cells.⁴⁸

Echinacea has immunostimulatory properties (reviewed in reference 49), and its extracts induce interleukin-1 α (IL-1 α), IL-1 β , IL-6, IL-10, and TNF from human and mouse macrophages *in vitro*.^{50,51} Lupus flares triggered by echinacea have not been reported, but flares of pemphigus vulgaris, an autoimmune disorder of the skin, have been reported after the ingestion of echinacea.⁵² In contrast, though, echinacea extract was safe and effective in controlling autoimmune uveitis.⁵³ The effects of echinacea on autoimmune disorders remain unclear, so it is generally recommended that lupus patients avoid echinacea-containing products.⁵⁴

Melatonin also stimulates the immune system by increasing expression of IFN- γ and IL-2 in human helper T cells and IL-1, IL-6, and IL-12 in human monocytes *in vitro*.⁵⁵ However, melatonin did block or slow the development of lupus in a mouse model of pristane-induced lupus⁵⁶ by decreasing anti-dsDNA antibodies, decreasing proinflammatory cytokines (IL-2, IL-6, IFN- γ , TNF- α , and IL-1 β), and increasing antiinflammatory IL-10. In separate studies, melatonin worsened disease in lupus-prone male Mrl/lpr mice but improved disease characteristics in female mice.^{57,58} Because of these contradictory data, melatonin and the sleep aid Rozerem, a melatonin receptor agonist, should be used with caution in lupus patients.

Extracts from garlic are considered because they increase lymphocyte proliferation and release of histamine from basophils and mast cells.⁵⁹ However, garlic extracts also increase antiinflammatory IL-10 and decrease proinflammatory cytokines (IL-1 α , IL-6, IL-8, IL-12, IFN- γ , TNF- α) from human monocytes treated *in vitro*.⁶⁰ No cases of lupus or lupus flares have been attributed to garlic, but use of garlic is discouraged in lupus patients because of its immunostimulatory properties.

LABORATORY FEATURES

Cytopenia is less common in DIL than in idiopathic lupus, and severe hematologic abnormalities are unusual. A positive Coombs test has been reported in association with procainamide, methyl dopa, and chlorpromazine. Rarely, methyl dopa may induce hemolytic anemia as well.^{61,62}

The ANA in DIL tends to have a homogeneous pattern, although a speckled pattern may also be seen.³ ANAs can persist for years after treatment with a drug is stopped, even after the symptoms resolve. Antihistone antibodies are found in 75% of DIL cases, but they are also found in 75% of idiopathic lupus cases, so it is not a specific test.⁶³ Antihistone antibodies are likewise seen in patients with rheumatoid arthritis, Felty syndrome, and undifferentiated connective tissue disease. Antihistone antibodies may persist even after use of the offending drug has stopped and the symptoms have resolved. The antihistone antibodies in idiopathic lupus are primarily against the H1 and H2B subunits. In contrast, the antihistone antibodies found in most DIL cases are directed against the H2A and H2B subunits. In the case of hydralazine, the antihistone antibodies are directed against the H1 and H3-H4 complex. Patients with procainamide-induced lupus tend to produce IgG antibodies against an (H2A-H2B)-DNA complex, whereas asymptomatic patients receiving procainamide are more likely to have IgM antibodies to H2A-H2B dimers lacking DNA. However, this restricted activity is not specific for DIL because IgG antibodies against the H2A-H2B dimer have been found in the sera of 15% to 20% of antihistone-positive patients with idiopathic lupus. Thus, the diagnostic value of antihistone antibodies is limited.⁶⁴⁻⁶⁷

Antibodies to single-stranded DNA (ssDNA) are similarly not specific for DIL. In contrast, antibodies to dsDNA are found in approximately half of patients with idiopathic lupus, but in less than 5% of those with DIL.^{13,68} Most notably, antibodies to Smith antigen appear to be very specific for idiopathic lupus because they are rarely found in DIL.⁶⁸ Finally, DIL also tends to be characterized by normal complement levels. However, a recent review reported a more frequent occurrence of elevated anti-dsDNA titers and low complement levels in anti-TNF-related DIL than in other types of DIL (i.e., not anti-TNF related).³⁸

Antiphospholipid antibodies, including lupus coagulant and anticardiolipin antibodies, have been reported in association with a number of drugs, but chlorpromazine, procainamide, and quinidine/quinine account for the majority of cases.⁶⁹ Chlorpromazine-induced antibodies are generally IgM and are not commonly associated with thrombosis. In contrast, the lupus anticoagulants induced by procainamide or quinidine/quinine are generally IgG and are associated with a higher incidence of thrombosis. In a small study, anticardiolipin antibodies, lupus anticoagulant, and thromboses developed in melanoma patients treated with IFN- α at or near the end of a 4-week regimen.⁷⁰ The rapid development of thromboses with IFN- α is unique when surveying other reports of drug-induced antiphospholipid antibodies, but the underlying melanomas being treated by IFN- α may also

be contributing. Notably, DIL anticoagulants resolve within weeks to months of stopping treatment with the suspected drug, but anticardiolipin antibodies can persist.⁶⁹

THERAPEUTIC OPTIONS

The symptoms of DIL generally resolve once treatment with the offending drug is stopped, so the most important aspect of treating DIL is recognizing that a drug is responsible for the illness. The development of a positive ANA while receiving a drug is not sufficient reason to discontinue the drug, although careful monitoring for subsequent clinical illness is important. Constitutional and musculoskeletal symptoms are usually controlled adequately with aspirin or other NSAIDs. Low-dose prednisone is occasionally necessary, and higher doses of prednisone may be used for resistant or symptomatic pericardial effusion. The rare cases of biopsy-proven renal disease or vasculitis should be treated with aggressive immunosuppression as for idiopathic lupus. Although most symptoms of DIL resolve within weeks of discontinuing treatment with the offending drug, occasional patients may take up to 1 year to recover completely.³

PATHOGENESIS

Even though methyl dopa and levodopa have similar chemical structures and hydralazine and isoniazid share a hydrazine side chain, the other molecules known to induce lupus have little in common. This suggests that no single chemical structure is responsible for inducing autoimmunity.

Instead, many lines of evidence show that DNA demethylation contributes to the pathogenesis of DIL. DNA methylation refers to the methylation of carbon 5 in cytosines to form deoxymethylcytosine (dmC). DNA methylation patterns are established during development by the “*de novo*” DNA methyltransferases 3a and 3b (Dnmt3a and Dnmt3b) and then are maintained by Dnmt1 each time that a cell divides. As cells enter mitosis, signals transmitted through the ERK and JNK pathways upregulate Dnmt1. When Dnmt1 encounters a dmC in the parent DNA strand, it catalyzes transfer of the methyl group from S-adenosylmethionine to the corresponding dC in the daughter strand, thereby replicating the methylation pattern. This is a crucial step because if DNA methylation is inhibited, either by preventing Dnmt1 upregulation or by interfering with the transmethylase reaction, the methylation patterns will not be replicated in the daughter cell. Consequently, genes that are normally silent can become demethylated and expressed. Furthermore, because the changes are heritable, the errors will be replicated during subsequent cell divisions. Thus, it is at this point that DNA methylation and consequently gene expression become sensitive to the environment.⁷¹

Inhibiting DNA methylation in CD4+ T cells makes them autoreactive by causing overexpression of the adhesion molecule LFA-1 (CD11a/CD18). LFA-1 normally binds ICAM-1 on antigen-presenting cells and surrounds the T-cell receptor–major histocompatibility complex (TCR-MHC). Such binding stabilizes the TCR-MHC interaction and provides additional co-stimulatory signals that result in T-cell activation when the TCR recognizes both the antigenic peptide and the MHC molecule. Treating CD4+ T cells with DNA methylation inhibitors such as 5-azacytidine (5-azaC) increases LFA-1 expression. This enables T cells to respond to lower-affinity interactions between the TCR and “self” class II MHC molecules without the appropriate antigen, thus making the T cells autoreactive. Autoreactivity also develops when T cells are transfected with LFA-1.⁷² These autoreactive T cells recognize and respond to self class II MHC molecules on B cells, with antibody production being overstimulated both through effects on cell-surface co-stimulatory molecules and by secretion of stimulatory cytokines such as IFN- γ .^{73,74} Autoreactive T cells also respond to self class II MHC molecules on macrophages and kill them by inducing apoptosis. This releases apoptotic chromatin from the dying macrophages,⁷⁵ which is highly antigenic. Genetic deletion of any of the molecules involved in clearing apoptotic material or overwhelming of the mechanisms that clear apoptotic materials causes lupuslike autoantibodies to nuclear antigens, including chromatin and DNA.^{76,77} Because macrophages are responsible for clearing apoptotic chromatin, macrophage apoptosis will further augment the autoantibody responses. Thus, T cells made autoreactive by inhibition of DNA methylation contribute to lupuslike autoimmunity by generating antigenic chromatin (macrophage apoptosis) and autoantibodies (B-cell stimulation).

The pathologic significance of demethylated CD4+ T cells was first demonstrated when murine CD4+ T cells treated with 5-azaC were injected into genetically identical mice. The modified cells caused anti-DNA antibodies and immune complex glomerulonephritis.⁷⁸ More recent studies

have used transgenic mouse models to confirm that inducing T-cell DNA demethylation by blocking ERK and JNK signaling *in vivo* causes lupuslike autoimmunity.⁷⁹⁻⁸¹

Procainamide and hydralazine, the two drugs that cause DIL most often, are inhibitors of DNA methylation. Treating CD4+ T cells with procainamide or hydralazine caused overexpression of LFA-1 and made CD4+ T cells autoreactive, just like 5-azaC did. Procainamide inhibits Dnmt1 enzymatic activity,⁸² whereas hydralazine prevents Dnmt1 upregulation during mitosis by inhibiting signaling via the ERK pathway.⁸³ Interestingly, N-acetylprocainamide, the acetylated metabolite of procainamide, does not cause DIL flares in patients with previous procainamide-induced lupus.⁸⁴ It is less potent in causing T-cell LFA-1 overexpression and autoreactivity *in vitro*, and it also has a reduced ability to cause autoimmunity in animal models.⁸⁵

It is not known whether the other drugs listed in Box 132.1 also affect DNA methylation. It is likewise not known whether DNA demethylation in cells other than T lymphocytes also contributes to DIL. Nonetheless, the adoptive transfer and transgenic mouse models demonstrate that T-cell DNA demethylation alone is sufficient to cause lupuslike autoimmunity.

CONCLUSION

Practicing physicians need to be aware of the potential problem of DIL. Prompt recognition and treatment are associated with an excellent outcome in most cases. The number of reported associations is expected to increase as new drugs are developed. Since some of these case reports may represent idiosyncratic reactions or the coincidental development of idiopathic lupus, rigorous epidemiologic, clinical, and laboratory testing should be done to confirm the association. Finally, physicians need to be aware that many patients with chronic diseases ingest over-the-counter alternative medicines that could potentially induce the development of autoimmune diseases, including lupus.

Acknowledgments

The authors would like to acknowledge the contributions of Drs. Melanie Joy and Mary Anne Dooley, who were the coauthors of this chapter in the previous edition.

Assessing disease activity and outcome in systemic lupus erythematosus

■ VIBEKE STRAND ■ ALVINA D. CHU

- Disease activity indices strive to capture the heterogeneous, multisystemic disease manifestations of systemic lupus erythematosus (SLE).
- In addition to disease activity, it is important to assess the impact of the disease, its treatment, and associated damage on the health-related quality of life of patients with SLE.
- It is challenging to design randomized controlled trials for SLE and to assess their outcome.
- Evidence-based composite responder indices appear to be best suited for assessing the treatment effects of investigational products.

INTRODUCTION

Systemic lupus erythematosus (SLE) is a heterogeneous, relapsing, remitting disease that affects many dimensions of a patient's life. Disease activity typically affects multiple organ systems without a predictable pattern, even in the same patient. In part because of earlier diagnosis and treatment, the survival rate of patients with SLE has increased to greater than 90% 5 years after diagnosis and to 80% 10 years after diagnosis, with fewer deaths being attributed to SLE since 1970.¹ No uniform therapeutic regimens have been established, and treatment is largely determined by physicians' judgment of patients' clinical outcomes. Rather than focusing on survival, outcomes in randomized controlled trials (RCTs) of SLE are designed to assess therapeutic responses.

In clinical practice, the patient's history, physical examination, and laboratory findings primarily guide assessment of disease activity and efficacy of treatment. The patient's history and physical examination should be comprehensive with a focus on the characteristic organ system involvement of SLE (see Chapter 126). Some laboratory features may also correlate with the signs and symptoms of SLE activity. Anemia, leukopenia, thrombocytopenia, hypocomplementemia (low C3 or C4 values, or both), elevated erythrocyte sedimentation rate, a rise in anti-double-stranded DNA antibody levels, or any combination of these features may be associated with increased SLE disease activity. Proteinuria, hematuria, urinary casts, and a rise in creatinine levels may signify renal involvement in SLE. Clinical and laboratory features should be interpreted together while keeping in mind other connective tissue diseases and nonrheumatic conditions that may be included in the differential diagnosis.

A variety of disease activity indices (DAIs), in addition to measures of damage, patient-reported fatigue, and health-related quality of life (HRQOL), have been designed to aid in the assessment of SLE. Although DAIs are used by some practitioners in clinical practice, they were developed for use in longitudinal observational studies (LOSs) and have subsequently been validated in RCTs. In 1998, an international consensus conference on outcome measures in rheumatology (OMERACT 4) recommended that four core domains be assessed in RCTs of SLE: disease activity, damage (because of SLE, its treatment, or both), HRQOL, and adverse events.^{2,3} The European League Against Rheumatism Task Force on SLE published similar

recommendations in 2009.⁴ A guidance document for the development of new therapeutic agents for patients with SLE issued by the U.S. Food and Drug Administration in 2010 encouraged the measurement of outcomes, including disease activity, damage, SLE flares, concomitant corticosteroid use, patient-reported outcomes, and biomarkers.⁵ Understanding the reasons supporting regular assessment of these domains will facilitate the ability to evaluate therapeutic responses in patients with SLE.

Because individual measures of clinical response in SLE reflect only a portion of what can be considered the "true outcome," it is important to consider disease activity within the context of the many effects of SLE on patient well-being.⁶ Thus, the strengths and limitations of organ system-specific and global DAIs and the generic and disease-specific measures of HRQOL must be understood and are best used together to complement each other.

DISEASE ACTIVITY INDICES

Four SLE DAIs have been used in RCTs: the Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) and its modifications, including the Safety of Estrogens in Lupus Erythematosus National Assessment (SELENA-SLEDAI), SLEDAI 2000 (SLEDAI-2K), and SLEDAI-2K 50%; the British Isles Lupus Assessment Group (BILAG) Index, classic and 2004 modification; the Systemic Lupus Activity Measure (SLAM and SLAM-R modification); and the European Consensus Lupus Activity Measure (ECLAM).⁶ They capture global or organ-specific manifestations (or both) attributed to SLE rather than secondary manifestations, including damage as a result of disease, its treatment, and associated comorbid conditions.

Systemic lupus erythematosus disease activity index

The SLEDAI and its modifications measure disease activity based on 24 questions assessing the clinical manifestations of SLE, including physical findings and laboratory values weighted across organ systems.⁷ Although the maximum score achievable is 105, even with very active disease, scores rarely exceed 20. Preferential weighting is based on the manifestations of vasculitis, central nervous system (CNS) involvement, and active renal disease. Modeled on clinicians' global judgment, the original SLEDAI was not intended to detect gradations of disease activity within an organ system: neither worsening nor partial improvement. Completed rapidly with minimal training, the SLEDAI has been cross-culturally validated with reproducibility and reliability by expert clinicians and trainees.⁶

In contrast to the original SLEDAI, which measures manifestations over the past 10 days, the SELENA-SLEDAI and SLEDAI-2K have been modified for use in RCTs to score manifestations over the past 28 to 30 days.^{8,9} They measure ongoing disease activity with improved clarification and attribution for individual items. The SLEDAI-2K descriptors, definitions, and weighted scores are presented in Table 133.1.¹⁰ Cross-sectional analysis of data collected by the SLEDAI-2K has indicated that the most appropriate cutoff score for active disease is 3 or 4.¹¹ Recently, to increase sensitivity in detecting improvement in disease, the SLEDAI-2K Responder Index-50 (S2K RI-50) was developed and validated in LOSs and found to reliably detect 50% improvement in the 24 descriptors, with partial improvement allowed to be acknowledged (see Table 133.1).^{12,13} A Web-based program is now available for training and use of the S2K RI-50.¹⁴

TABLE 133.1

Systemic Lupus Erythematosus Disease Activity Index 2000 (SLEDAI-2K)¹⁰ and SLEDAI-2K Responder Index-50¹² improvement definitions

Descriptor		SLEDAI-2K score and definitions	SLEDAI-2K Responder Index-50 improvement definitions (summarized)
Seizure	8	Recent onset; excludes metabolic, infectious, or drug causes	≥50% reduction in the frequency of baseline seizures (days/mo)
Psychosis	8	Altered ability to function in normal activity because of a severe disturbance in the perception of reality. Includes hallucinations, incoherence, marked loose associations, impoverished thought content, marked illogical thinking, and bizarre, disorganized, or catatonic behavior. Excludes uremia and drug causes	≥50% improvement in psychotic manifestations as judged by a physician
Organic brain syndrome	8	Altered mental function with impaired orientation, memory, or other intellectual function; rapid onset and fluctuating clinical features; inability to sustain attention on the environment; plus at least 2 of the following: perceptual disturbance, incoherent speech, insomnia or daytime drowsiness, or increased or decreased psychomotor activity. Excludes metabolic, infectious, or drug causes	≥50% improvement in organic brain manifestations as judged by a physician
Visual	8	Retinal changes of SLE. Includes cytooid bodies, retinal hemorrhages, serous exudate or hemorrhages in the choroid, or optic neuritis. Excludes hypertension, infection, or drug causes	≥50% improvement in findings on retinal examination as assessed by a physician
Cranial nerve	8	New onset of sensory or motor neuropathy involving the cranial nerves	≥50% recovery of motor or sensory function in the affected nerve or a ≥50% decrease in the severity of pain within 1 mo from the event on the basis of a decrease in lupus disease activity without worsening in either
Lupus headache	8	Severe, persistent headache; may be migrainous, but must be nonresponsive to narcotic analgesia	≥50% decrease in the severity of pain as determined by the patient on a numerical scale of 1-10
Cerebrovascular accident	8	New onset of CVA. Excludes arteriosclerosis	≥50% recovery of motor or sensory function related to a CVA within 1 mo from the event on the basis of a decrease in lupus disease activity as determined by a physician without worsening in either
Vasculitis	8	Ulcerations, gangrene, or tender finger nodules; periungual infarction; splinter hemorrhages; or biopsy or angiographic proof of vasculitis	≥50% improvement in the vasculitis lesions present with no new lesion or worsening in either
Arthritis	4	≥2 joints with pain and signs of inflammation (i.e., tenderness, swelling, or effusion)	≥50% reduction in the number of joints with pain and signs of inflammation (i.e., tenderness, swelling, or effusion)
Myositis	4	Proximal muscle aching/weakness associated with elevated creatine phosphokinase/aldolase or electromyographic changes or a biopsy specimen showing myositis	≥50% increase in muscle power or ≥50% decrease in the level of creatine phosphokinase/aldolase with no worsening in either
Casts	4	Hem-granular or red blood cell casts	≥50% decrease in the total number of casts (heme-granular and red blood cell casts)
Hematuria	4	>5 red blood cells/high-power field. Excludes stone, infection, or other cause	≥50% decrease in the number of red blood cell/high-power field at this visit
Proteinuria	4	>0.5 g/24 hr	≥50% decrease in the range of proteinuria
Pyuria	4	>5 white blood cells/high-power field. Excludes infection	≥50% decrease in the number of white blood cells/high-power field
Rash	2	Inflammatory-type rash	≥50% decrease in the involved body surface area and/or activity of most active lesion with no worsening in either
Alopecia	2	Abnormal, patchy or diffuse loss of hair	≥50% decrease in the total scalp area involved by patchy alopecic lesions or ≥50% reduction in diffuse alopecia with no worsening in either
Mucosal ulcers	2	Oral or nasal ulcerations	≥50% decrease in the number of ulcers at this visit
Pleurisy	2	Pleuritic chest pain with a pleural rub or effusion or pleural thickening	≥50% reduction in pain severity and/or ≥50% reduction in the amount of fluid (on imaging) with no worsening in either
Pericarditis	2	Pericardial pain with at least 1 of the following: rub, effusion, or electrocardiographic or echocardiographic confirmation	≥50% reduction in pain severity and/or ≥50% reduction in the amount of fluid (on imaging) with no worsening in either
Low complement	2	Decrease in CH ₅₀ , C3, or C4 below the lower limit of normal for the testing laboratory	≥50% increase in the level of any complement or normalization of 1 of them without a drop in either
Increased DNA binding	2	Increased DNA binding by the Farr assay above the normal range for the testing laboratory	≥50% reduction in the level of anti-DNA antibodies
Fever	1	>38° C. Excludes infectious cause	≥50% reduction in the degree of fever above normal
Thrombocytopenia	1	<100,000 platelets/mm ³ ; excludes drug causes	≥50% increase in the level of platelets, but <100,000 platelets/mm ³
Leukopenia	1	<3000 white blood cells/mm ³ ; excludes drug causes	≥50% increase in the level of white blood cells, but <3000 white blood cells/mm ³

CH₅₀, 50% hemolyzing dose of complement; CVA, cerebrovascular accident; SLE, systemic lupus erythematosus.

British isles lupus assessment group disease activity index

The BILAG was developed to measure disease activity in individual organ systems based on an intent-to-treat principle.¹⁵ The BILAG 2004 is a major revision of the “classic BILAG” and expands the scoring of manifestations within organ systems to nine: constitutional, mucocutaneous, neuropsychiatric, musculoskeletal, cardiorespiratory, gastrointestinal, ophthalmic, renal, and hematologic¹⁶; ophthalmic was added, previous abdominal and hepatic manifestations were combined into a single gastrointestinal category, and vasculitis was redistributed into the specific organ system of involvement. Eighty-six items are scored for SLE disease activity occurring within the past 4 weeks versus the previous month. Scores are converted into letter categories representing the need for therapy (Table 133.2). The BILAG and BILAG 2004 are the only DAIs that score features as improved, the same, worse, or new rather than as present or absent. A single numeric summary score has been developed for the classic BILAG and BILAG 2004, similar to the global score generated by the SLEDAI, although it is a discontinuous measure.¹⁶ Table 133.3 presents a comparison of the key components of SLEDAI-2K and BILAG-2004.

As with SLEDAI-based indices, the BILAG and BILAG 2004 have been used as outcome measures, as well as to define eligibility criteria for RCTs.¹⁷ Scoring rules for this detailed and comprehensive instrument are outlined for the user, and effort is made to ensure accuracy of reporting by those less familiar with use of the BILAG. Internet-based training courses, computer-assisted scoring, and independent formal adjudication panels have been used in RCTs to address variability in interpretation and scoring of the BILAG. Importantly, adjudication of BILAG scoring ensures that the physical examination findings and laboratory results accurately reflect reported improvements or worsening in disease manifestations. The BILAG and

BILAG 2004 are not generally used in clinical practice despite computerized programs available for scoring.

Systemic lupus activity measure and European Consensus Lupus Activity Measure

The SLAM is based on signs and symptoms observed over the past 4 weeks, with weighting of more severe clinical manifestations. It uniquely includes patient-reported symptoms of fatigue. In the more recent revised index, SLAM-R, scores range from a minimum of 0 to a maximum of 81.¹⁸ The ECLAM scores nine clinical and three laboratory manifestations of SLE over the past 4 weeks, with scores ranging from 0 to 10; physician global assessment of disease activity (PGA) is the reference “gold standard.”¹⁹

Lupus flare definitions

Multiple definitions are used to define flare in SLE, some adapted from the DAIs summarized earlier. The SELENA-SLEDAI Flare Index (SFI) was developed as the primary endpoint for the SELENA RCTs to define mild/moderate versus severe flares; it incorporates the SELENA-SLEDAI score, corticosteroid use, and PGA score to determine flare severity.^{8,9}

“Mild/moderate” flares are defined as new or worsened clinical features resulting in increases in the SELENA-SLEDAI score of 3 or more points, prednisone use less than 0.5 mg/kg/day, PGA score of 1.0 to 2.5 on a 0 to 3 visual analog scale (VAS), or any combination of these measures. Severe flares are defined as changes in SELENA-SLEDAI scores to higher than 12 or clinical manifestations requiring doubling of the prednisone dose or an increase to 0.5 mg/kg/day or greater.

“Severe” flares have been defined by the BILAG as the development of a new “A” or two simultaneous “B” scores in any organ system and “moderate” flares as a new BILAG B score from previous B, C, D, or E scores.²⁰ No definition for a “mild” flare based on the BILAG index has been validated.

A pragmatic definition of a “major” flare as defined by Fortin and colleagues^{21,22} included new or increased use of immunosuppressive therapy, new or increased use of corticosteroids at 0.5 mg/kg daily or greater, and hospitalization or death because of SLE disease activity. These straightforward criteria typically do not require adjudication in RCTs.

The SFI, BILAG, and Fortin definitions of flare have been used in RCTs, and some trials have used more than one definition. To reach a consensus on a single definition of flare in SLE, an international effort sponsored by the Lupus Foundation of America was initiated in 2006 to develop a clinically meaningful definition of flare for use in RCTs, LOSs, and clinical practice: “A flare is a measurable increase in disease activity in one or more organ systems involving new or worse clinical signs and symptoms and/or laboratory measurements. It must be considered clinically significant by the assessor and usually there would be at least consideration of a change or increase in treatment.”²³ Specific criteria to distinguish between mild, moderate, and severe flares remain to be established.

Measures of damage

The relapsing, remitting, and chronic nature of SLE results in irreversible damage over time as a result of the disease, its treatment, or both. The Systemic Lupus International Collaborating Clinics (SLICC)/American

TABLE 133.2
Scoring of BILAG and BILAG-2004 for each organ system

Letter categorization	Definition
A	Severe disease requiring increases in prednisone to >20 mg daily and/or the addition of immunosuppressive agents
B	Less active disease requiring low-dose prednisone and/or symptomatic treatment with nonsteroidal antiinflammatory drugs and/or antimalarials
C	Mild disease requiring symptomatic therapy such as simple analgesics or stable disease on current therapy
D	Previous organ system involvement without current disease activity
E	No previous or current disease involvement in that organ system

BILAG, British Isles Lupus Assessment Group.

TABLE 133.3
Comparison of the BILAG 2004 and SLEDAI-2K Disease Activity indices

	BILAG 2004	SLEDAI-2K
Method of development	Physician intention to treat categorized by organ system	Delphi consensus by physician and statistician panel
Number of manifestations	86	24
Time frame considered	Previous 28 days	Previous 10 or 30 days
How scored	Improved, same, worse, new, not present	Present or absent
Score	A-E “intention-to-treat” categories; numerical scoring also available	Numerical scoring: 0-105
Weighting	None	Greatest for CNS and vascular involvement
Laboratory variables considered	Proteinuria, creatinine, glomerular filtration rate, urinary sediment, anemia, leukopenia, neutropenia, thrombocytopenia, active hemolysis, Coombs test positivity	Casts, hematuria, proteinuria, pyuria, low complement, increased DNA binding, thrombocytopenia, leukopenia

BILAG, British Isles Lupus Assessment Group; CNS, central nervous system; SLEDAI, Systemic Lupus Erythematosus Disease Activity Index.

College of Rheumatology Damage Index (SDI) was developed to capture damage from disease activity, medications, and comorbid conditions that has been present for 6 or more months with the intent of identifying irreversible damage. Twelve organ systems are assessed, with a maximum of 47 points.²⁴ The SDI reflects the impact of disease distinct from disease activity, with early accumulation of damage being associated with a poor prognosis and increased mortality.²⁵ However, typically it has not performed well in RCTs in differentiating active from control therapy and may best be used as an entry criterion to balance randomization.

Other measures of damage include organ-specific definitions of worsening or loss of function, such as the urinary protein-creatinine ratio or glomerular filtration rate based on timed urine samples or the presence of osteopenia or osteoporosis secondary to SLE, its treatment with corticosteroids, or both.⁶

OTHER OUTCOME MEASUREMENTS

Health-related quality of life

HRQOL is defined as the impact of disease on the physical, psychological, mental, and social aspects of health, as influenced by the expectations and life experiences of an individual patient.²⁶ It is important to assess HRQOL in SLE, especially since it has clearly been shown that disease activity, damage, and HRQOL are independent of each other and thus reflect different domains affected by disease.³ Both generic and disease-specific measures have been used in RCTs and LOSs in SLE.

The Medical Outcomes Short Form 36-Item Survey (SF-36) is a generic instrument that is widely used for rheumatic and nonrheumatic diseases; it includes eight domains: physical functioning, role physical, bodily pain, general health perceptions, vitality (which includes fatigue, energy, and pep), social functioning, role emotional, and mental health impact.²⁷ The physical component summary score (PCS) positively weights four “physical” domains—physical functioning, role physical, bodily pain, and general health perceptions, as well as vitality—and negatively weights the remaining three. The mental component summary score (MCS) positively weights the four “mental” domains—vitality, social functioning, role emotional, and mental health impact—and negatively weights the 4 physical domains. The SF-36 has best reflected the impact of SLE on HRQOL in LOSs and frequently has been the only patient-reported outcome in RCTs,^{27,28} or utilized with a measure of fatigue.^{29,30} Minimum clinically important differences

have been defined for improvements in the PCS and MCS (2.5) and individual domain (5.0) scores, as well as for deterioration (−0.8 and −2.5, respectively).^{31,32}

Patients with SLE most commonly complain of fatigue and an inability to engage in activities important to them.^{33,34} The SF-36 queries fatigue in the vitality domain, also including “pep and energy” and two specific measures of fatigue, the Krupp Fatigue Severity Scale (KFSS) and the Functional Assessment of Chronic Illness Therapy—Fatigue (FACIT-F), which have been used and validated in RCTs of SLE and nonrheumatic diseases.³⁵ The KFSS, a nine-item scale, measures the impact of fatigue on specific types of functioning, such as motivation, exercise, and work, family, or social life.³⁶ The FACIT-F includes 13 fatigue-related items that assess the impact of fatigue on usual activities, eating, and social activity over the past 7 days.³⁷

Recognition that generic HRQOL measures may not include all issues important to patients with SLE has led to the development of several disease-specific questionnaires (Table 133.4).^{38–40} All are at different stages of development and validation cross-culturally and geographically for use in multinational RCTs, as well as in daily clinical practice. The Lupus Quality of Life tool (LupusQoL), developed in the United Kingdom, has been translated and cross-culturally validated in 13 languages, for use in the United States, Canada, France, Germany, and Spain, and is to date the only one with published RCT data.⁴¹ This has been accomplished on a smaller scale by a comparison of the generic SF-36 with LupusQoL in a cohort of 41 patients at one site in Canada; it was demonstrated that together, both instruments offer complementary information.^{28,42} The Systemic Lupus Erythematosus Quality of Life tool (SLE-QoL), developed and validated in Singapore, measures the physical and psychological aspects of SLE; 40 items are summed to yield a global score.⁴³ Patients rate specific items based on their frequency and importance over the past month. Unlike the LupusQoL, the SLEQoL places less emphasis on physical functioning and pain.⁴⁴

The Lupus Patient-Reported Outcome tool (LupusPRO) was developed and validated based on feedback from an ethnically heterogeneous SLE population from the United States across both genders.⁴⁰ It includes issues pertinent to men with SLE: physical and mental health, cognition, procreation, body image, and effects of SLE medications, as well as items not considered to reflect HRQOL, such as desires, goals, coping, social support, and satisfaction with care. Rapidly completed in less than 10 minutes, it is designed to identify areas of HRQOL that require further, repeated assessment. To aid in the use of an SLE-specific HRQOL measurement in daily practice on a monthly basis, a shorter questionnaire derived from 10 of the LupusPRO items, the Lupus Impact Tracker, was derived for use in clinical

TABLE 133.4
SLE-specific health-related quality-of-life instruments

Name	Features	Scoring	Where developed
Lupus Quality of Life tool (LupusQoL)	34 items distributed over 8 domains: physical health, pain, planning, intimate relationships, burden to others, emotional health, body image, fatigue	Each domain scored separately with no global score	UK; cross-culturally adapted and validated for use in the US, Canada, and France, with translations available in multiple European, Latin American, and Asian languages
Quality of Life in SLE (L-QoL)	Assesses the overall impact of SLE and its treatment on 25 items based on the needs of the patient	Responses (true or not true) are summed, with higher scores indicating poorer health	UK
Systemic Lupus Erythematosus Quality of Life (SLE-QoL)	40 items covering 6 domains: physical functioning, activities, symptoms, treatment, mood, self-image	Global score; a higher score indicates worse HRQOL	Singapore; cross-culturally adapted for use in Chinese-speaking patients in Singapore (SLEQoL-C)
Lupus Patient-Reported Outcome tool (LupusPRO)	44 items across 10 HRQOL domains: lupus symptoms, lupus medication, physical health, emotional health, pain, vitality, procreation, cognition, body image, general health; also included are 4 “non-HRQOL” domains: desires-goals, coping, social support, satisfaction with care	HRQOL and non-HRQOL scores derived by the mean of the relevant domains and transformed to scores ranging from 0 (worst QOL) to 100 (best QOL). A higher score signifies better health	US
Lupus Impact Tracker	A 10-item subset of the LupusPRO covering fatigue, pain, performance of usual activities, fulfillment of family responsibilities, ability to plan activities, anxiety, depression, concentration, self-image, and medication side effects	Global scores ranges from 0 to 40 and is converted to a lupus impact score that ranges from 0 to 100; a higher score signifies poorer HRQOL	US

HRQOL, health-related quality of life; SLE, systemic lupus erythematosus.

TABLE 133.5
Responder indices used in randomized controlled trials

Responder index	Method of derivation	Criteria to define “response”
Responder index for DHEA trials	FDA-sponsor consensus	No treatment failure Improvement in the SLEDAI or SLAM without deterioration in the other Improvement in patient global assessment or the KFSS without deterioration in the other
Response Index for Lupus Erythematosus (RIFLE)	Delphi process	Complete response based on resolution of abnormal signs in specific organ systems, including renal, neurologic, mucocutaneous, and musculoskeletal Partial response based on decreased features of disease within an organ system but not full resolution
SLE Responder Index (SRI)	Phase 2 data mining	No new or increased use of proscribed medications or early dropout ≥4-point reduction in the SELENA-SLEDAI score No new BILAG A or >1 new B scores No PGA deterioration from baseline >0.3 points
British Isles Lupus Assessment Group–based Composite Lupus Assessment (BICLA) endpoint	Phase 2 data mining	Reduction of all baseline BILAG A and B scores No new BILAG A or 2 new B scores No worsening in baseline SLEDAI or PGA scores No treatment failure

BILAG, British Isles Lupus Assessment Group; DHEA, dihydroepiandrosterone; FDA, Food and Drug Administration; KFSS, Krupp Fatigue Severity Scale; PGA, physician global assessment of disease activity; SELENA, Safety of Estrogens in Lupus Erythematosus National Assessment; SLAM, Systemic Lupus Activity Measure; SLEDAI, Systemic Lupus Erythematosus Disease Activity Index.

practice and shown to accurately reflect the impact of SLE on patients’ lives and well-being.^{45,46}

Global assessments of lupus disease activity

Most RCTs involving SLE query PGA but not patient global assessment of disease activity (PtGA). As in rheumatoid arthritis, the appropriate question is phrased, “In all the ways your disease affects you today, how are you doing?” on a 0 to 100 mm VAS scale. Responses correlate with answers to the transition question in the SF-36, “Compared with a year ago, how is your general health today?”⁶ It should be noted that PGA and PtGA offer information from different perspectives; patients’ perceptions of the impact of their disease may be associated with psychosocial stressors that may not be apparent to the physician, who will focus on assessment of disease activity and damage, including CNS and renal manifestations, which may be less obvious to the patient. Thus, it is not uncommon find that PGA and PtGA do not correlate well in RCTs.^{3,6}

Composite responder indices

Responder indices define patients who have improved with treatment versus those who have not based on multiple components. Composite responder indices require improvements based on different outcome measures that generally do not correlate closely with each other, thereby adding power and decreasing the sample sizes required for RCTs; those used in recent RCTs are listed in Table 133.5.⁶ In addition to the specific components defined within each index, “responses” first require that patients not be “treatment failures,” as defined prospectively in each trial. Definitions of treatment failure typically include withdrawal because of adverse events or the use of prohibited medications.

The Response Index for Lupus Erythematosus was defined according to specific improvements in organ system manifestations as determined by a Delphi consensus process, but it did not differentiate between active and control therapy when included in an RCT.⁶ In recent phase 3 RCTs, composite responder indices were designed based on data mining of phase 2 studies of belimumab and epratuzumab: the SLE Responder Index (SRI) and the BILAG-based Combined Lupus Assessment (BICLA), respectively (see Table 133.5).⁴⁷⁻⁴⁹ These indices demonstrated the importance of developing evidence-based responder indices.^{50,51} Responses on the SRI are based on no “treatment failure” and improvement of 4 or more points in the

SELENA-SLEDAI score, without worsening of the BILAG by one “A” or two simultaneous “B” scores and “no deterioration” in PGA by more than –0.3 points on a 0 to 3 scale. The SRI was subsequently used as the primary endpoint in two successful phase 3 RCTs: BLISS-76 and BLISS-52, one for “validation” and the other for confirmation.

Similarly, in the BICLA, responses are based on no “treatment failure,” loss of all “A” or “B” BILAG scores, and no worsening of the total SLEDAI score and “no deterioration.” It is the predefined primary endpoint in the ongoing phase 3 studies of epratuzumab, EMBODY 1 and 2.^{48,49}

CONCLUSION

It should be noted that no single regimen is accepted as standard-of-care therapy for SLE and that the choice of treatment is dependent on the active disease manifestations in an individual and the treating rheumatologist. Outcome measures in RCTs assessing investigational treatments must account for individual differences, as well as previous and current use of background corticosteroid and immunosuppressive medications. Changing background therapy during the course of a trial may mask any potential benefit from the investigational therapy. To maximize the ability to identify the treatment benefit of an investigational agent added to background therapy it is critical to use responder indices, predefine the use of corticosteroids and immunosuppressive agents, and restrict changes in their doses.⁶

Over the past 3 decades, existing DAIs and definitions of flare have been refined, and damage- and disease-specific HRQOL instruments and evidence-based responder indices have been developed. Nonetheless, the heterogeneous multisystemic nature of SLE poses a unique challenge in assessing outcomes in clinical practice, as well as in RCTs. No one DAI is sufficient to capture responses to therapy, nor is it possible to accurately identify all the aspects of a patient’s life that are affected by SLE at any given time. Disease activity, including recognition of flares and damage as a result of the disease and its treatment, HRQOL, and global assessment of disease activity should be evaluated when measuring outcomes in daily practice, as well as in RCTs—provided that instruments exist that may be pragmatically used in each setting.⁶ Development and further refinement of composite responder indices that include components that can be used in clinical practice will facilitate better understanding of the results from RCTs, as well as translate their utility into day-to-day use.

Management of nonrenal and non-central nervous system lupus

■ DANIEL J. WALLACE

- Quality of life and prognosis can be improved without prescribing lupus medication by screening for lupus comorbidities (e.g., accelerated atherogenesis, osteoporosis) and by encouraging lifestyle modifications (e.g., smoking cessation, exercise).
- Lupus medications for non-organ-threatening disease include topical antiinflammatory agents, nonsteroidal antiinflammatory drugs, antimalarials, and low doses of corticosteroids when needed.
- Methotrexate, mycophenolate mofetil, azathioprine, and cyclophosphamide account for 95% of all prescriptions of immunosuppressive drugs for treatment of systemic lupus erythematosus (SLE) and are employed to reduce steroid use and ameliorate organ-threatening disease.
- Only one targeted therapy (belimumab) is approved for treatment of SLE. Several other biologic agents on the market may have niche roles in treating active disease.

INTRODUCTION

The management of lupus erythematosus involves a variety of approaches, including physical measures, education, surgery, and medication. A large number of interventions are available that are relevant and can affect outcome and prognosis.¹ These include lifestyle measures and preventive strategies.

GENERAL MANAGEMENT CONSIDERATIONS

A patient newly diagnosed with lupus or one new to a practice setting is better equipped to deal with the disease if the treating physician has an educational session with the patient and with those closely involved in the patient's care (Box 134.1). This session should include a review of physical and lifestyle measures, distribution of brochures or information relating to access to patient resources, discussion of coping mechanisms, overview of relevant therapeutic approaches, emphasis on the importance of adherence to the treatment regimen, and consideration of all concerns or questions. Fatigue is present in 50% to 90% of patients with systemic lupus erythematosus (SLE) and can be one of its most debilitating symptoms.² Causes include inflammation, medication, fibromyalgia, psychosocial distress, infection, cytokine dysregulation, hormone imbalances, and comorbidities (e.g., anemia, interstitial lung scarring, malnutrition). Fatigue is managed by treating the underlying cause (e.g., with antiinflammatory therapies) and by instructing the patient to pace activities, follow good sleep hygiene practices, engage in aerobic exercise, obtain emotional support, and avoid stimulants unless medically supervised. Aerobic capacity is decreased by 30% to 40% in SLE patients and correlates with obesity, fatigue, bone demineralization, reduced cardiovascular functioning, muscle atrophy, and decreased quality of life. Exercise, particularly isometric as opposed to isotonic strengthening regimens if synovitis is present, improves these factors.³ Smoking can be harmful in lupus via several mechanisms: it can worsen Raynaud syndrome, decrease tissue oxygenation, cause deleterious effects because of the presence of hydrazines in tobacco smoke, and interfere with the effectiveness of hydroxychloroquine.⁴ Modest use of alcohol has no influence on SLE. Lupus patients are sensitive to alterations in barometric pressure and thus experience more stiffness, and seasonality may play a role,

with aggravation of Raynaud syndrome in winter months and increased ultraviolet light exposure during the summer. Individuals with SLE do not take more pain medication than the general population unless comorbidities such as avascular necrosis or fibromyalgia are present. The use of opiates is generally unnecessary and is potentially harmful.

The role of stress and trauma in lupus is controversial, but the following have been observed: (1) Discoid lupus lesions can occur in scars from prior skin trauma. (2) Although results from animal models (e.g., the Lewis rat, which has a hypofunctioning CRH neuron) suggest that a lupuslike disorder can result from abnormal stress responses, there is no evidence that physical or emotional trauma can induce SLE. (3) A majority of patients with lupus associate flares with physical or emotional trauma, but evidence-based studies have not been able to confirm this perception.⁵ Optimizing coping mechanisms with counseling, biofeedback, anxiety reduction measures, and cognitive behavioral therapy improves outcome and prognosis. The rates of adherence⁶ in the United States with regard to keeping appointments, filling prescriptions, and following physician advice relating to lupus (e.g., sun avoidance) ranges from 40% to 90%.

Lupus patients should avoid alfalfa sprouts (which contain high concentrations of L-canavanine) and echinacea (which can act as an immune activator), should eat one or two fish meals a week or take fish oil capsules (eicosapentaenoic acid is antiinflammatory), and should not be deficient in immune regulation-enhancing vitamin D (low levels are associated with more disease activity and can result from sun avoidance). There is no specific lupus diet except for dietary measures to reduce risks from corticosteroid use and protein-sparing diets in patients with advanced renal impairment.⁷ Over 50% of lupus patients use complementary and alternative medicine approaches.⁷ As long as these approaches do no harm and are not a substitute for accepted lupus therapies, there is no need to avoid them.

Preventive strategies that improve outcome

A variety of approaches can improve outcome and prognosis in lupus patients without the use of any antiinflammatory or disease-modifying medications. The best-documented interventions involve sun avoidance and sun protection measures⁸ (Box 134.2). Ultraviolet A (UVA) and UVB light enhance the antigenicity of epidermal DNA, allowing anti-Ro (if present) to be exposed to the cell surface and provoking an inflammatory response via apoptotic blebs. Sun exposure is greatest at midday and at higher altitudes. Sun sensitivity is self-reported in two thirds of individuals with SLE and is confirmed by objective phototesting in one third. Commercially available sunscreens consist of ultraviolet light-absorbing chemical agents in cream, oil, lotion, alcohol, gel, or foam vehicles that can block UVA, UVB, or both. Outpatients should use agents with a sun protection factor (SPF) of at least 15, which blocks 93% of UVB rays; a sunscreen with an SPF of 50 blocks only 5% more. Broad-spectrum protection is present if UVA-2 is also blocked in addition to UVB (UVA-1 might actually help lupus).

Caution should be exercised in administering live attenuated vaccines to those taking immunosuppressive drugs, but household transmission from healthy individuals receiving such vaccines have not been reported. Routine immunizations such as influenza, pneumococcus, and hepatitis B vaccinations are safe, but their potency may be impaired.⁷ The prevalence of reactivity to nonarylamine sulfa antibiotics (which are sun sensitizing) is increased among lupus patients, and their use should be considered on an individual basis. One third of SLE patients have antiphospholipid antibodies, and one third of these patients experience a thromboembolic event. Individuals with high-risk thrombogenic profiles should be evaluated to determine whether they are candidates for thromboprophylactic interventions. Such interventions include treatment with low-dose aspirin, warfarin, heparin, or platelet antagonists. See Chapter 139.

BOX 134.1 GENERAL MANAGEMENT CONSIDERATIONS TO REVIEW WITH LUPUS PATIENTS

1. Education: Explain what lupus is and its causes. Provide educational literature and Web/resource listings.
2. Physical and lifestyle measures: Provide recommendations on diet, exercise, physical measures, immunizations, smoking cessation, and sun protection, and emphasize the importance of adherence to the treatment regimen.
3. Emotional support: Counsel on how to deal with fatigue and on coping and stress-reduction strategies.
4. Adjunctive measures: Provide information on health maintenance (e.g., gynecologic examinations, colonoscopy, annual physical examinations, eye examinations), screening for accelerated atherogenesis, complications of medications, and osteoporosis. Emphasize the need to establish a relationship with a primary care provider who will communicate with the lupus physician.

BOX 134.2 SUN PROTECTION AND SAFE SUN HABITS

- Outdoor activities should be scheduled before 10 AM and after 4 PM.
- Up to 80% of ultraviolet (UV) rays penetrate cloud cover and can be reflected from water, concrete, sand, snow, tile, and reflective glass in buildings. Extra care is important at higher altitudes.
- Clothing is an excellent form of sun protection, especially loose-fitting, lightweight dark clothing, sunglasses, and broad-brimmed hats.
- Protective clothing blocking UV-B light with a sun protection factor of 30 or higher is commercially available online. Sunblocks should be applied 15 to 30 minutes before sun exposure and can be applied liberally. UV-A protection is also desirable. Sunscreens should not be applied to broken skin or rashes.
- UV-B sunblocks with avobenzone and zinc oxide also blocks UV-A1 rays, and titanium dioxide products are the best for very sensitive skin.
- Sunblocks are available as creams, lotions, gels, sprays, lotions, and sticks and in waterproof and heat-resistant forms, as well as in lip and eyelid formulations.

Fractures have been reported in 5% to 21% of individuals with SLE. Inflammation, use of glucocorticoids, vitamin D deficiency, renal dysfunction, ovarian failure, and hypothyroidism are the most common associations with osteoporosis in lupus patients.⁹ Bone densitometry should be performed at 1- to 2-year intervals in patients at higher risk. Preventive strategies include adequate supplementation with vitamin D and calcium and appropriate antiresorptive therapies when indicated.

A clear-cut demarcation of who is responsible for treating which aspect of the care of the lupus patient—primary care physician or lupus specialist—may be lacking. This is unfortunate, because coordination of care between these providers is critical. SLE patients are at increased risk of accelerated atherogenesis.¹⁰ They should be screened and treated for hypertension, hyperlipidemia, glucose intolerance, and atherosclerotic disease. Preventive strategies can clearly influence morbidity, mortality, and quality of life.

Local therapies

Topical corticosteroids are the most effective local treatment for cutaneous manifestations of lupus.⁶ These medications are available as fluorinated or nonfluorinated preparations and are sold in differing potencies in a variety of vehicles such as ointments, gels, creams, and lotions. Fifty years of experience have guided practitioners to the optimal following regimen: (1) non-fluorinated (over-the-counter) creams are weak but safe for long-term use, especially for facial lesions. (2) Fluorinated steroids are quite effective but should never be used on a facial lesion for longer than 2 weeks (otherwise, they will lead to cutaneous atrophy and telangiectasias). (3) Ointments are 80% absorbed, whereas creams are only 20% absorbed (but are better tolerated); most other vehicles fall in between. (4) Intralesional injections or occlusive dressings ameliorate focal areas of inflammation. (5) Ninety percent of all lupus prescriptions are written for one of three preparations: desonide (mild potency), triamcinolone (moderate potency), or clobetasol (high potency). Topical calcineurins are approved by the U.S. Food and Drug Administration (FDA) for eczema and can be applied with or without corticosteroids for cutaneous disease. These include pimecrolimus creams and tacrolimus ointments. Controlled trials have documented their modest efficacy for treatment of lupus rashes, and they are safe for long-term use in adults.¹¹ (Their use is associated with a very small increased risk of lymphoma in children.)

BOX 134.3 ACTIONS OF ANTIMALARIAL AGENTS THAT APPLY TO SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)**Physiologic effects**

Blockade of the effects of Toll-like receptors 3, 7, and 9 through alteration of pH or competitive inhibition that decreases innate immune system activation
Inhibition of phospholipase A₂ and phospholipase C
Stabilization of lysosome membranes
Decreased production of estrogen
Hypoglycemic, antihyperlipidemic, and antithrombotic actions
Ultraviolet light protection
Antiangiogenic effects
Inhibition of B-lymphocyte stimulation (BLyS, BAFF)

Clinical consequences

Hydroxychloroquine has sustained beneficial effects on overall survival, disease-free survival, and damage accrual.
Hydroxychloroquine delays the onset of SLE and reduces the number and severity of clinical flares.
Antimalarials protect against thrombosis, renal damage, and major infections in SLE.

BAFF, B-cell activating factor; BLyS, B-lymphocyte stimulator.

Nonsteroidal antiinflammatory drugs

Over 70% of lupus patients use one of the nonsteroidal antiinflammatory drug (NSAID) preparations on an intermittent or regular basis, mostly for fever, headache, myalgias, arthralgias, arthritis, and/or serositis.¹² NSAIDs can be safely prescribed to most lupus patients provided patients are closely monitored on a regular basis. NSAIDs should be used in pregnancy only occasionally and with great caution. Topical NSAIDs (diclofenac or keto-profen gel, salicylates) are safer and should be considered as a first-line treatment for local or regional inflammation. The majority of lupus patients who take NSAIDs on a frequent basis report that it improves their quality of life and diminishes pain.

Antimalarials

Antimalarials have been used to manage lupus since the 1950s, and over 300 million people have been prescribed these drugs for rheumatic disorders worldwide since that time (see Chapter 55). Ninety-five percent of all prescriptions are for hydroxychloroquine (HCQ). Chloroquine is usually reserved for refractory skin lesions, and quinacrine is given to patients who have a retinal contraindication for use of chloroquines. It is sometimes recommended for patients with profound fatigue or is used in combination with chloroquines.

Lupus-specific mechanisms of action

The mechanisms of action of the antimalarials relevant to lupus are noted on Box 134.3 and include an antagonist effect on the nucleic acid-sensing Toll-like receptors (TLRs), especially TLR3, TLR7, TLR8, and TLR9.¹³ This decreases the activation of the innate immune system via plasmacytic dendritic cells and interferon- α .

Clinical outcomes for lupus in evidence-based studies

A Canadian cooperative trial examining the use of HCQ to treat SLE in 1990 first demonstrated the agent's ability to reduce flares and decrease the risk of organ-threatening dissemination.¹⁴ Data from other cohorts documented the importance of HCQ in managing lupus, including, a sustained effects on overall survival, disease-free survival, and damage accrual.¹⁵ HCQ may even delay the onset of lupus, reduces clinical flares, and is most efficacious if used early in the disorder. Antimalarials improve survival in a time-dependent manner. The drugs are protective against thrombosis and have lipid-lowering properties, especially in patients taking corticosteroids. HCQ has beneficial effects on glycemic status and has a protective effect against renal damage and the development of major infections. There is a suggestion that it diminishes the activity of associated Sjögren syndrome and is safe in pregnancy.

Recommended community use, monitoring, and safety issues

HCQ is associated with an 80% clinical response rate at 3 months when used in doses of 5 mg/kg/day for non-organ-threatening disease.¹³ Increased

TABLE 134.1

Usual regimens of systemic glucocorticoid (GC) therapy in systemic lupus erythematosus (SLE)*

GC regimen	Representative indications	Common adverse effects (AEs)
Pulse GC (PGC)[†]		
≥250 mg PDNeq/day × 1-5 days Typically 0.5-1 g MP/day IV × 1-3 days, administered monthly as indicated; usually given with oral GC (30-60 mg PDNeq/day)	Life- or organ-threatening complications (e.g., RPGN, myelopathy, severe acute confusional state, alveolar hemorrhage, vasculitis, optic neuritis) [‡] HDGC-refractory disease DPGN or severe FPGN [§]	Same as with HDGC (see later), but overall incidence of AEs may be lower, partly because PGC may allow more rapid taper of oral GC doses. Special considerations due to large dose and route of administration: fluid overload, hypertension, neuropsychiatric symptoms. Rarely: cardiac arrhythmias or sudden death, myalgias/arthritis, seizures, intractable hiccups, GC anaphylaxis.
Very-high-dose GC (VHDGC)[†]		
>100 mg PDNeq/day IV/PO (start with divided doses)	Life- or organ-threatening complications (as for PGC) [‡]	Same as but more severe than with HDGC. Psychosis. Risk of severe or fatal infection may be particularly high (avoid use for longer than 1-2 wk).
High-dose GC (HDGC)[†]		
>30 mg and ≤100 mg PDNeq/day IV/PO	DPGN or severe FPGN (for less than 6-8 wk) [§] Thrombocytopenia, hemolytic anemia Acute lupus pneumonitis, "lupus crisis"	AEs are same for both HDGC and MDGC but incidence and severity are lower with the latter. HPA axis suppression, Cushing syndrome, hypertension, hypokalemia, hyperglycemia, hyperlipidemia, atherosclerosis, OP, ON, risk of infection, skeletal growth retardation, glaucoma, cataracts, skin fragility, acne, insomnia, steroid psychosis, mood swings, etc.
Moderate-dose GC (MDGC)[†]		
>7.5 mg and ≤30 mg PDNeq/day IV or PO	Moderate SLE flares (e.g., myositis, severe pleurisy, ophthalmoplegia [except optic neuritis], thrombocytopenia) With PGC or CYC/AZA for severe disease	AEs are same for both HDGC and MDGC but incidence and severity are lower with the latter. HPA axis suppression, Cushing syndrome, hypertension, hypokalemia, hyperglycemia, hyperlipidemia, atherosclerosis, OP, ON, risk of infection, skeletal growth retardation, glaucoma, cataracts, skin fragility, acne, insomnia, steroid psychosis, mood swings, etc.
Low-dose GC (LDGC)[†]		
≤7.5 mg PDNeq/day PO	Arthritis, mild constitutional symptoms (unresponsive to analgesics/NSAIDs/AM). Generalized lymphadenopathy Maintenance therapy	Least toxic daily regimen. Cataracts, GC withdrawal symptoms (upon tapering to or below LDGC). Skeletal growth retardation can occur. Infection rates are still increased but are lower than with higher dosages. Probably minimal OP, ON, HPA axis suppression.
Alternate-day GC (ADGC)		
	Membranous nephritis with nephrotic syndrome (120 mg PDNeq) During tapering of GC dose. Maintenance therapy (e.g., 15 mg PDNeq for glomerulonephritis)	Decreased AEs (e.g., HPA axis suppression, skeletal growth retardation, infection, Cushing syndrome) compared with daily regimens. OP can occur.

*All PDNeq dosages assume a 60-kg patient; adjustments should be made for patients of different weights.

[†]Adopted from the recommendations of the First European Workshop on Glucocorticoid Therapy.²⁰[‡]CYC therapy, usually IV, is often needed as well.[§]In combination with IV CYC.^{||}"Lupus crisis" refers to acute and severe illness with high fever, extreme prostration, and other symptoms of active SLE (e.g., pleurisy, arthritis, vasculitic rash) in patients who requires large dosages of GC for disease control and in whom infection has, of course, been excluded as the cause of the symptoms.

AM, antimetabolites; AZA, azathioprine; CYC, cyclophosphamide; DPGN, diffuse proliferative glomerulonephritis; FPGN, focal proliferative glomerulonephritis; HPA, hypothalamic-pituitary-adrenal; IV, intravenous; MP, methylprednisolone; NSAIDs, nonsteroidal antiinflammatory drugs; OP, osteoporosis; ON, osteonecrosis; PDNeq, prednisone equivalent; PO, orally; RPGN, rapidly progressive glomerulonephritis.

From Albert DA, Hodler NM, Ropes MW. Does corticosteroid therapy affect the survival of patients with systemic lupus erythematosus? *Arthritis Rheum* 1979;22:945-53.

dosing up to 7 mg/kg/day can manage flares but generally should not be prescribed for longer than 3 months. Up to 10% of patients discontinue the drug during the first few months of use due to rash, gastrointestinal effects, or constitutional complaints. Because HCQ can induce corneal edema and retinal pigmentation (the latter occurs in 3% of patients who have used the drug for 10 years or longer), the American Academy of Ophthalmology recommends that baseline screening should be performed during the first few months of therapy and again at 5 years followed by annual examinations.¹⁶ Chloroquine is usually given at a dosage of 500 mg daily for the first 1 to 2 months, after which treatment is transitioned to HCQ or dosing is gradually tapered to 250 mg as 1 to 2 tablets a week. Chloroquine is much stronger and more toxic than HCQ. Quinacrine is available from compounding pharmacies and is started at 25 to 100 mg daily. The potential for gastrointestinal adverse effects, lichen planus-like rashes, and bone marrow suppression warrant vigilance, with blood testing every 1 to 2 months.

Corticosteroids

Several large studies in the 1950s documented life-saving beneficial effects of corticosteroids in treating a variety of complications of lupus. Since that time, although several large surveys have demonstrated efficacy for renal and central nervous system (CNS) lupus, very few studies have specifically evaluated the use of these drugs for other manifestations of the disorder. Their short-term effects are dramatic, but in the long term they play a role in worsening morbidity and mortality from lupus. For organ-threatening disease, corticosteroids are often prescribed in combination with immunosuppressive steroid-sparing regimens.¹⁷

Lupus patients are prescribed corticosteroids for their antiinflammatory and immunosuppressive effects.¹⁸

Clinical use and experience

Seriously ill patients are administered pulse steroids (1 g daily of intravenous methylprednisolone for several days), a regimen that has additional

pharmacologic effects^{17,18} (Table 134.1). Individuals with stable lupus can be prescribed alternate-day dosing as maintenance, which diminishes immunosuppression and infection risk and is less inhibitory of adrenal responsiveness. Intramuscular steroids include triamcinolone, methylprednisolone, dexamethasone, or betamethasone; effects lasts several weeks to months and can ameliorate constitutional and musculoskeletal flares. Some of these preparations can also be used intraarticularly. Dexamethasone has a theoretical advantage in managing CNS disease because it more readily crosses the blood-brain barrier. The most commonly used oral preparation is prednisone, which is given once daily but can also be dosed every 8 to 12 hours in acutely ill patients, in whom it is metabolized more rapidly. Prednisolone is very similar and may be preferred in children with maturing hepatic function. Intravenous hydrocortisone is efficacious in 15 to 20 minutes (as opposed to 2 hours for intravenous methylprednisolone) but the duration of action is only 4 to 6 hours.

In large lupus cohorts, 80% to 90% have received one of these agents during the course of their disease. Larger studies and a meta-analysis of 52 reports published through the 1960s demonstrated that steroids improved survival but actually did not significantly alter outcome in patients with mild to moderate disease.¹⁹ In a randomized, prospective, double-blind, placebo-controlled flare prevention study, short-term corticosteroid therapy prevented severe flares in 154 SLE patients who were evaluated monthly for 18 months.²⁰ In another cohort, low-dose daily prednisone was not associated with a substantially increased risk of irreversible organ damage.²¹

High-dose daily corticosteroids are efficacious for life- or organ-threatening autoimmune hemolytic anemia, immune thrombocytopenia purpura, bone marrow hypoplasia, acute myocarditis, acute lupus pneumonitis, mesenteric vasculitis, autoimmune pancreatitis, optic neuritis, and retinal vasculitis associated with severe, active SLE. Treatment is usually prescribed at a dose of 1 mg/kg/day of prednisone equivalent for 2 to 4 weeks. A dramatic response is often followed by a slow tapering of approximately 10% per week. If the manifestation is refractory to treatment or if tapering to 10 mg/day of prednisone equivalent cannot be achieved, steroid-sparing immunosuppressive regimens of targeted therapies can be added.

A few non-CNS or nonrenal manifestations of lupus warrant consideration of **pulse corticosteroids** as induction therapy followed by high-dose daily corticosteroids, including any of the aforementioned complications as well as thrombotic thrombocytopenic purpura, Stevens-Johnson syndrome-like skin reactions, severe acute cutaneous disease, or alveolar hemorrhage.

Moderate-dose daily corticosteroids (considered to be 0.25 to 0.5 mg/kg/day of prednisone equivalent) may be given for 2 to 4 weeks followed by tapering for treatment of acute pleurisy or pericarditis, flares of thrombocytopenia, active rashes, or lupus myositis, among other manifestations.

Low-dose daily corticosteroids (less than 10 mg of prednisone equivalent daily) are the mainstay for persistent, chronic, active disease, especially with musculoskeletal, constitutional (fatigue, fever, adenopathy), cutaneous, and serous membrane manifestations or combinations of these.

Complications and monitoring

Long-term steroid use is associated with cutaneous atrophy (from topical fluorinated steroids), ecchymosis, capillary fragility, avascular necrosis, hyperglycemia, increased susceptibility to infection, hyperlipidemia, hypertension, pancreatitis, osteoporosis, cataracts, glaucoma, double vision, alterations in mood and behavior, peptic ulcer disease, fluid retention, weight gain, and many other toxicities.²² Long-term steroid use also is associated with accelerated atherogenesis.

Immunosuppressive therapies

Immunosuppressive agents used for the treatment of nonrenal, non-CNS lupus erythematosus are reviewed here. Cyclophosphamide, methotrexate, azathioprine, and mycophenolate mofetil account for 95% of all prescriptions of immunosuppressive drugs used in SLE, and up to 40% of all lupus patients take one of these agents at some point in their disease. These drugs are rarely used as monotherapy but are almost always given in combination with NSAIDs, antimalarials, and corticosteroids.

Alkylating agents: cyclophosphamide, chlorambucil, nitrogen mustard

Alkylating agents have been used to manage lupus since nitrogen mustard was reported to be beneficial for cutaneous disease in 1947.²³ In view of the toxicity of nitrogen mustard and chlorambucil, neither of these agents has any place in the management of lupus. Cyclophosphamide (CYC) is a

BOX 134.4 STEROID-SPARING REGIMENS USEFUL IN TREATING NONRENAL, NON-CENTRAL NERVOUS SYSTEM COMPLICATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

nitrogen mustard alkylating agent that has been available since the early 1960s. A prodrug, it is converted by mixed-function oxidase enzymes in the liver to active metabolites. Twenty percent of CYC is excreted by the kidney and 80% is processed in the liver. In SLE, CYC works via direct functional effects on lymphocytes, producing a dose-related lymphopenia, T- and B-cell depletion, and alterations of macrophage function and gene transcription resulting in decreased pathogenic autoantibody production.²⁴ CYC is usually given intravenously at low dosages (Eurolypus regimen, or 500 mg every 2 weeks for six cycles), high dosages (National Institutes of Health regimen, 750 mg/m² monthly for 6 months with an option of every 2 to 3 months for 2 to 3 years), or ablative dosages (e.g., 50 mg/kg/day for 4 days for stem cell transplantation induction).^{25,26} It can also be prescribed orally (especially for vasculitis) in dosages ranging from 25 to 100 mg daily. CYC is the most potent immunosuppressive agent used in SLE and can be employed as monotherapy or prescribed in combination with corticosteroids and other immunosuppressive agents.

Almost every study using a lupus protocol containing CYC has limited its enrollment to patients with CNS or renal involvement. Several reports examining the use of CYC for treatment of “severe connective tissue disease crisis” in 90 patients in London (most of whom had lupus) documented a trend toward dramatic improvement.²⁷ Case series have suggested efficacy for patients with acute life- or organ-threatening complications of lupus such as alveolar hemorrhage, autoimmune hemolytic anemia and thrombocytopenia, optic neuritis, thrombotic thrombocytopenic purpura, and mesenteric vasculitis. Ablative regimens are too toxic to be recommended. Rarely, low-dose daily oral CYC has a place in treating selected refractory cases of inflammatory arthritis or vasculitis (Box 134.4).

The use of antiemetics such as ondansetron, adequate hydration, and the addition of 2-mercaptoethane (mesna) allow CYC to be better tolerated and safer when administered to patients with SLE. There is evidence that the monthly administration of leuprolide acetate (3.75 mg subcutaneously) 2 weeks before a dose of CYC decreases the incidence of premature ovarian failure.²⁸ Infection risks correlate directly with white count nadirs of less than 3000 cells/mm³. Long-term use is associated with a greater risk of malignancy, especially bladder cancer and gynecologic dysplasias.

Azathioprine

Azathioprine (AZA) is a purine synthesis inhibitor converted in the body to the active metabolites 6-mercaptopurine and 6-thioinosinic acid. It reduces numbers of circulating B and T lymphocytes, immunoglobulin synthesis, and CD28-mediated costimulation.²⁹ The majority of prescriptions written for AZA in SLE patients are for treatment of nephritis. Its nonrenal indications include inflammatory arthritis, severe cutaneous disease, pneumonitis, hepatitis, protein-losing gastroenteropathy, autoimmune hemolytic anemia, and thrombocytopenia. AZA is not very effective as induction monotherapy, but in combination with corticosteroids, the agent is steroid sparing and decreases flare rates. It is commonly prescribed in combination with other immunosuppressive regimens and targeted therapies.^{30,31}

Dosing is usually initiated at 50 mg daily orally for the first week and built up to 150 mg daily, or about 3 mg/kg/day, over several weeks. Approximately 10% of patients are unable to tolerate the drug due to deficiency of the enzyme thiopurine methyltransferase (TPMT) and experience nausea, bone marrow toxicity, rash, or fever.³² Measurement of TPMT activity before initiation of therapy may identify patients at greatest risk of bone marrow suppression (i.e., those homozygous for the deficiency). If this test is not available, then starting at a low dose and building up slowly with frequent complete blood count monitoring is usually a satisfactory means of safely administering the drug. AZA is associated with an increased risk of skin cancer, human papillomavirus-induced cancers, and, after 10 to 20 years of continuous use, lymphoma.³³ Although it is classified as a pregnancy category D drug, AZA has a well-established safety record as an option for lupus patients who wish to conceive.

Mycophenolate mofetil

Mycophenolate mofetil (MMF) is a prodrug of mycophenolic acid that inhibits inosine-5'-monophosphate dehydrogenase. By preferentially depleting guanosine nucleotides in T and B-lymphocytes, it inhibits their proliferation, thereby suppressing cell-mediated immune responses and antibody formation.³⁴

The use of MMF for treatment of SLE has been studied since 1990, but no controlled trials were conducted until after 2000. Lupus nephritis is the principal indication for MMF and is the reason for treatment in a large majority of patients taking the drug. Dosages range from 500 mg/day in transplant patients to 3 g/day with those with active nephritis, but most patients are prescribed 1500 to 2000 mg/day in divided doses. A small number of studies have evaluated the use of MMF for nonrenal and non-nervous system manifestations. It has a rapid onset of action compared with other immunosuppressives in that effects can be observed in 2 to 4 weeks. The author's group reviewed results in 75 patients given MMF for any indication and demonstrated a more than 50% improvement in composite British Isles Lupus Assessment Group (BILAG) scores in half of the patients. It might be steroid sparing as well.³⁵ Although MMF is prescribed for pemphigoid and lichen planus lesions by dermatologists, it appears to be ineffective for chronic cutaneous lupus. There is limited evidence that it has some efficacy for hematologic or pulmonary involvement in SLE.³⁶ Gastrointestinal adverse effects or intolerance has been reported in 10% to 30% of lupus patients given MMF. The author recommends that MMF be considered after methotrexate or AZA for nonrenal, non-CNS lupus.

Methotrexate

Few evidence-based studies of the use of methotrexate (MTX) in SLE have been conducted, and only two enrolled more than 40 subjects. A double-blind, prospective, randomized, controlled trial involving 41 patients concluded that 15 to 20 mg of MTX weekly for 6 months was significantly effective in controlling cutaneous and articular activity of SLE as measured by Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) scores and was steroid sparing.³⁷ In a 12-month, double-blind, placebo-controlled trial of MTX involving 86 patients, the agent was steroid sparing (22% reduction in dose), slowed damage scores, and reduced disease activity as measured by the revised Systemic Lupus Activity Measure (SLAM) score.³⁸ MTX is most effective for articular, cutaneous, serosal, and constitutional

manifestations of SLE.³⁹ Dosages of 10 to 25 mg weekly are recommended, but if renal impairment is present, dosing at levels of 10 mg a week or less is advised.

Leflunomide

Leflunomide was found to be significantly more effective than placebo in treating mild to moderate lupus, especially lupus with arthritis, based on SLEDAI scores.⁴⁰ Leflunomide has been used in Asia for treatment of nephritis, but there is no experience with its use for this indication in North America or Europe.

Cyclosporine

In lupus studies cyclosporine has been found to have a definite niche use for specific complications that do not respond to other treatments: cytopenias (especially bone marrow aplasias), oral ulcerations, eczema-like lesions, urticaria, and nephritis.⁴¹ A randomized, controlled trial involving 89 patients with severe SLE demonstrated that cyclosporine was as effective a steroid-sparing agent as AZA.³¹ The author usually prescribes 100 mg twice daily and finds that cyclosporine can clear skin lesions within days.

Niche therapies and specialized approaches

Approximately 10% of patients with nonrenal, non-nervous system SLE may benefit from treatments outside of the usual NSAID, antimalarial, corticosteroid, and routine immunosuppressive regimens at some time in the course of their disease.⁴²

Antileprosy drugs

Dapsone inhibits folic acid and para-aminobenzoic acid, blocks the alternate pathway of complement activation, promotes neutrophil cytotoxicity, and is a mild anti-tumor necrosis factor (anti-TNF) agent. It has been used in selected cases of cutaneous vasculitis, bullous lupus, urticaria, oral ulcerations, lupus panniculitis, and subacute cutaneous lupus.⁴³ Thalidomide and lenalidomide have similar actions, are teratogens, and improve refractory cutaneous disease but may have an unacceptable risk-benefit profile because of associated neuropathy and procoagulant action.⁴⁴

Other immune-modulating and immunosuppressive agents

Tacrolimus is used primarily for treatment of nephritis, and its topical forms improve cutaneous lupus. Rapamycin is an anti-transplant rejection agent that is under study in a phase 2 trial for treatment of SLE. Mizoribine is a purine antagonist similar to AZA used widely in Japan. Fludarabine, cytarabine, and cladribine are antineoplastic agents that are too toxic for use in lupus patients. Antilymphocyte and antithymocyte globulin is used in lupus patients as part of stem cell protocols. Retinoids (e.g., acitretin) can be helpful for subacute cutaneous lupus and refractory skin lesions but are sun sensitizing.⁴⁵ Intravenous immune globulin is used to treat nearly every complication of the disease, and studies suggest that this very expensive intervention is beneficial for thrombocytopenia, immunoglobulin G subclass deficiency, and chronic inflammatory demyelinating polyneuropathy.⁴⁶

Hormonal interventions

Dehydroepiandrosterone (DHEA) has modest effects on disease activity and is available over the counter, but its application for approval in the treatment of SLE was rejected by the FDA.⁴⁷ Little if any benefit is seen for the prolactin-blocking agent bromocriptine.⁴⁸ The impeded androgen danazol is prescribed in rare cases for the treatment of autoimmune hemolytic anemia or thrombocytopenia. A controlled trial of testosterone failed to meet its primary endpoint.⁴⁹

External procedures used to achieve a medical effect

Plasmapheresis (including plasma exchange) is used in SLE for thrombotic thrombocytopenic purpura, cryoglobulinemia, neuromyelitis optica, pulmonary hemorrhage, and hyperviscosity syndrome.^{50,51} It has relative short-term benefits for severe, organ-threatening disease in patients unresponsive to high-dose steroids and immunosuppressives.

Laser therapy is occasionally used for telangiectasias and refractory discoid lesions. Photopheresis is occasionally used for refractory skin manifestations. Cold UVA light in the 340 to 400 nm spectrum has antiinflammatory effects and is prescribed in infrequent cases. Total lymphoid irradiation is effective but is far too toxic for SLE patients, and lymphocytapheresis is generally ineffective.

Fig. 134.1 Summary of results of the BLISS-52 and BLISS-76 phase 3 studies of belimumab for treatment of systemic lupus erythematosus. Figure shows percentage of patients demonstrating improvement at week 52 as judged by the Systemic Lupus Erythematosus Responder Index (SRI). (Adapted from Navarra SV, Guzman RM, Gallacher AE, et al. Efficacy and safety of belimumab in patients with active systemic lupus erythematosus: a randomized, placebo-controlled, phase 3 trial. *Lancet* 2011;377:721-31; Furie R, Petri M, Zamani O, et al. A phase III, randomized, placebo-controlled study of belimumab, a monoclonal antibody that inhibits B lymphocyte stimulator, in patients with systemic lupus erythematosus. *Arthritis Rheum* 2011;63:3918-30.)

Targeted therapies

Approved in March 2011, belimumab is the only targeted therapy approved by the FDA for treatment of lupus. It is indicated for autoantibody-positive disease with ongoing activity. A human monoclonal antibody to soluble (not membrane-bound) B-lymphocyte stimulator, belimumab was studied in phase 2 and 3 trials with over 2000 participants.⁵²⁻⁵⁴ It produced significant improvements as measured by an instrument known as the *Systemic Lupus Erythematosus Responder Index*, which included a four-point reduction in SLEDAI score, no real organ domain involvement (one BILAG A score or two BILAG B scores), and no more than a 10% reduction in physician global assessment (Fig. 134.1). Approximately 70% of patients receiving the drug respond in 3 to 6 months after being given monthly doses of 10 mg/kg administered over 1 hour, preceded by three infusions over a month as a loading dose. Belimumab appears to be steroid and immunosuppressive sparing and has an excellent safety profile. The author prescribes it for patients who have active disease despite treatment or are intolerant of corticosteroids and immunosuppressive regimens.

Other targeted therapies on the market but not approved for treatment of SLE include abatacept, rituximab, anti-TNF therapies, and anakinra. Abatacept did not meet its primary endpoint in an industry-sponsored nephritis and nonnephritis trial. The Immune Tolerance Network of the National Institutes of Health is conducting an ongoing study, and its post-hoc analysis of data from the industry-sponsored trial suggested that abatacept is beneficial.^{55,56} The anti-CD20 chimeric monoclonal antibody rituximab failed to meet its primary endpoints in both nephritis and non-nephritis trials.^{57,58} However, both studies mandated that the placebo and rituximab arms of the protocol include the administration of highly effective therapies: high-dose corticosteroids and immunosuppressives. Both groups improved, and the underpowered study and its open-label follow-up were discontinued prematurely. There is evidence from cohort studies and case series that selected patients with lupus arthritis, hemolytic anemia, and thrombocytopenia respond to this agent, and it has demonstrated efficacy when added to traditional steroid and immunosuppressive regimens. The use of anti-TNF therapies or anakinra in SLE is poorly studied, but these agents do not appear to be of any significant benefit.

A variety of innovative targeted therapy approaches are currently under study (Table 134.2).⁵⁹ Stem cell therapies should be considered only in patients with life-threatening complications of SLE for whom all other appropriate interventions have failed.

TREATMENT OF LUPUS ERYTHEMATOSUS WITH MEDICATION

General principles

Lupus runs the gamut from disease requiring no specific antiinflammatory treatment to life- and organ-threatening manifestations for which intensive therapeutic protocols are indicated. If organ involvement is present (e.g., cardiopulmonary, renal, hepatic, or CNS involvement, cytopenias), patients are usually managed with high-dose corticosteroids and immunosuppressive

TABLE 134.2

Targeted therapies in systemic lupus erythematosus

Mechanism of action	Examples of targets
T cells	CTLA4-Ig; modified CD40L mAb; ICOS; expansion of CD4+CD25+ cells, CD8+CD28- cells
B cells	mAbs to CD20, CD22, proteasome/plasma cells; anti-BlyS, TACI-Ig, BAFF-RFc
Complement	Anti-C5a
Cytokines	mAbs to sIL-6R, IL-6, IL-10, IL-17, IL-18, anti-TNFs
Innate immune system	Anti-IFN- α and IFN- γ ; blockade of TLR7 and/or TLR9
Toleragens	Peptides derived from nucleosomes, Sm Ag, Igs, 16/6 idiotype, spliceosome
Inhibition of cell surface receptor activation	Syk-kinase inhibition; sirolimus

BAFF-RFc, B cell activating factor-rasette-forming cells; BlyS, B-lymphocyte stimulator; ICOS, inducible costimulatory; IFN, interferon; Ig, immunoglobulin; IL, interleukin; mAb, monoclonal antibody; sIL, soluble interleukin; Sm Ag, Smith antigen; TACI, transmembrane activator and calcium republishing initiator; TLR, Toll-like receptor; TNF, tumor necrosis factor.

Adapted and updated from Wallace DJ. Advances in drug therapy for systemic lupus erythematosus. *BMC Med* 2010;8:77.

agents. Failure to use corticosteroids in this situation often results in significant organ damage. Non-organ-threatening involvement is approached with nonsteroidal drugs, antimalarial agents, and, if necessary, low-dose corticosteroids and immunosuppressive drugs. Lupus is a multisystem disease, and the treatment is usually more inclusive than, for example, just managing a rash, because a patient with a rash may also have fatigue, aching, or fevers.

Constitutional manifestations

The presence of fatigue, fever, weight loss, or malaise resulting from active inflammatory SLE, and no other factors such as infection or anemia, warrants a trial of a moderate-dose (0.5 mg/kg/day) prednisone equivalent for several weeks.

Cutaneous and cutaneous disease

Acute cutaneous lupus erythematosus represents active systemic disease and is nonscarring and transient. It is managed in the short term with moderate-dose corticosteroids.⁶⁰ Chronic cutaneous lupus erythematosus (discoid lupus) necessitates use of the sun protection measures and topical therapies discussed earlier in the chapter.⁶¹ The medications characteristically used for treatment are the antimalarial drugs. HCQ is the agent of choice, followed by quinacrine if chloroquines are contraindicated (e.g., in cases of retinal

disease) or if severe fatigue is present. Chloroquine can be used short term for treatment of severe rashes, after which patients are usually transitioned to treatment with HCQ. Subacute cutaneous lupus erythematosus responds to the aforementioned measures but can be more resistant to antimalarial agents and amenable to the addition of retinoids.⁶² Lupus profundus and bullous lupus respond to MMF or dapsone in addition to antimalarials.

Generalized cutaneous manifestations of lupus include oral ulcerations, malar rashes, alopecia, and urticaria. Specific interventions for these signs include treatment with cyclosporine (especially for urticaria) or triamcinolone in a dental gel for oral ulcerations, along with buttermilk or hydrogen peroxide gargles for oral ulcerations. The author prescribes nonfluorinated steroids, a short course of fluorinated steroids, tacrolimus, or pimecrolimus for the butterfly rash of lupus. Hair loss is common and frustrating and is often the last manifestation to improve after a flare. Intralesional steroid injections, cysteine-based shampoos, and minoxidil-based hair products are among numerous adjunctive therapies.

Cutaneous manifestations of SLE include Raynaud syndrome, chilblain, cutaneous vasculitis, and livedo reticularis.⁶³ The latter generally is not treated. Vasomotor instability in lupus is approached with cold-preventive measures, biofeedback, and cognitive-behavioral therapy. Calcium channel blockers (especially nifedipine), 5-phosphodiesterase blockers (e.g., sildenafil) for mild to moderate activity, and the addition of prostaglandins, bosentan, or antiinflammatory agents for digital vasculitis or gangrene can be beneficial. Sometimes chilblain responds to aspirin in addition to the aforementioned measures.

Musculoskeletal lupus

NSAIDs, antimalarial drugs, and corticosteroids all improve the synovitis and inflammatory arthritis seen in SLE.⁶⁴ The choice of therapy depends on the area of involvement, duration and severity of symptoms, and amount and degree of disease activity outside of the musculoskeletal system. When necessary, MTX, leflunomide, AZA, or anti-TNF regimens (but not MMF) also can be ameliorative. Five percent to 10% of patients with SLE have a mild myositis (creatinine phosphokinase levels of less than 1000), which responds to several weeks of 0.5 mg/kg/day of prednisone equivalent or less.

Cardiopulmonary disease

Serositis (pericarditis, pleurisy) responds immediately to NSAIDs and corticosteroids. Antimalarial agents improve it over weeks to months.⁶⁵ Acute lupus pneumonitis and pulmonary hemorrhage are life-threatening complications and require high-dose corticosteroids with or without CYC or apheresis.⁶⁵ Interstitial lung disease is a chronic process that takes years to evolve and is most often seen in overlap syndromes and associated Sjögren syndrome. It is managed with corticosteroids and immunosuppressives. Assessment for pulmonary hypertension should be part of baseline screening in most patients with lupus. Present in 2% to 5% of lupus patients, this serious complication is managed with vasodilator therapy, anticoagulation, and endothelial cell activation antagonists, but antiinflammatory regimens can lower pressures as well. Pulmonary embolism should be considered in any lupus patient with an acute onset of chest pain and shortness of breath and warrants anticoagulant therapy.

Outside of the pericardium, myocarditis and endocarditis are infrequently observed manifestations of lupus.⁶⁶ Most myocarditis is viral in origin (even in lupus patients), but lupus myocarditis warrants a short trial of high-dose corticosteroids. Myocardial dysfunction and microvascular angina are far more common than previously thought and are treated with β -blockers and nitrates. Coronary arteritis is very rare and responds to short courses of high-dose corticosteroids. Libman-Sacks endocarditis warrants further evaluation to rule out a superimposed bacterial endocarditis or immune complex vegetation, which might embolize. Blood-thinning and antimicrobial measures may be instituted.

Hematologic disorders

Anemias are common in lupus, especially in young women with heavy periods. Replacement regimens improve iron deficiency and vitamin B₁₂ deficiency.⁶⁷ Decreased bone marrow activity is representative of lupus-associated anemia of chronic disease and responds to disease-modifying therapies. Autoimmune hemolytic anemia is a serious complication of SLE and warrants high-dose corticosteroids along with immunosuppressive agents and/or targeted therapies (e.g., rituximab).⁶⁷ Leukopenias represent active inflammation and are also a complication of immunosuppressive regimens. Qualitative platelet dysfunction may occur, for which there is no optimal therapy; idiopathic thrombocytopenic purpura is managed with corticosteroids, immunosuppressive therapies, intravenous immune globulin, rituximab, and/or splenectomy. Thrombotic thrombocytopenic purpura is a life-threatening complication of lupus and the cause of death in 1% to 5% of cases; it is treatable with apheresis, steroids, and rituximab.⁶⁸

Miscellaneous nonrenal, non-nervous system complications

Rare but serious manifestations of SLE include retinal vasculitis, mesenteric vasculitis, and pancreatitis, which are treated with high-dose corticosteroids and immunosuppressive regimens once thromboembolic and drug causes are ruled out.

SUMMARY

Lupus is a pleomorphic disorder. When a patient comes for treatment of recent-onset disease, the first step is to stage the disease and assess what areas are involved. Once this is accomplished, a single physician should ideally oversee management of the disease in concert with a treatment team. Nonmedication interventions such as providing patient education, working with the mind-body connection, screening for comorbidities, and initiating prevention measures (e.g., sun avoidance) have been shown to improve prognosis. Non-organ-threatening disease is additionally managed with NSAIDs, antimalarial drugs, low-dose corticosteroids, and infrequently immunosuppressive or targeted therapy regimens. Severe lupus usually mandates an induction course of high-dose corticosteroids and the addition of immunosuppressives and consideration of targeted therapies. The prognosis of SLE has improved greatly over the last few decades as more treating physicians have adopted a multidisciplinary treatment approach.

135 Treatment of neuropsychiatric lupus

■ JOHN G. HANLY ■ ANTONINA OMISADE ■ JOHN D. FISK

- In patients with systemic lupus erythematosus (SLE), nervous system events are diverse, are common, and negatively impact health-related quality of life.
- Approximately one third of neuropsychiatric events in SLE patients are attributable to lupus.
- Diagnostic tests, including neuroimaging and assessment of cognitive function, are used to support the findings on clinical evaluation.
- Therapeutic intervention must be tailored to individual patients' needs and includes symptomatic and supportive therapies in addition to lupus-related immunosuppression and anticoagulation.
- Defined immunopathogenic mechanisms help to inform the selection of specific treatment strategies.

INTRODUCTION

The reported prevalence of neuropsychiatric (NP) disease in systemic lupus erythematosus (SLE) is highly variable (21% to 95%),¹ as is the prognosis following an NP event. This may reflect differences in study methodology, bias in the selection of patients, or a change over time in global disease severity. Many classifications of NP events in SLE lack definitions of individual manifestations as well as standardized methods for investigation and diagnosis. In 1999 the American College of Rheumatology (ACR) produced a standard nomenclature and case definitions for 19 NP syndromes² that are known to occur in SLE patients. These can be segregated into central and peripheral NP syndromes or studied individually (Table 135.1). For each of these NP syndromes potential causes other than SLE were identified, either for exclusion or as an "association." This component of the ACR classification, in combination with other variables, provides a framework for determining the attribution of NP events.

CAUSES OF NEUROPSYCHIATRIC SYSTEMIC LUPUS ERYTHEMATOSUS

NP events attributed to SLE (NPSLE) are primary manifestations of the disease, in contrast to complications of the disease (e.g., hypertension) or of its treatment (e.g., infection) (Fig. 135.1). Recent studies suggest that all nervous system events, regardless of cause, have a significant negative impact on health-related quality of life and that up to one third of NP events in SLE patients are attributable to SLE.¹ NP events due to lupus are likely a consequence of *vascular abnormalities*, *autoantibodies*, and *inflammatory mediators*.¹ Evidence from animal and human studies suggests two separate and potentially complimentary autoimmune pathogenic mechanisms for NPSLE (Fig. 135.2): (1) *vascular injury* involving large- and small-caliber vessels mediated by antiphospholipid antibodies, immune complexes, and leukoagglutination; clinical sequelae include focal NP events such as stroke and diffuse NP events such as cognitive dysfunction; (2) *inflammation-mediated injury* with increased permeability of the blood-brain barrier, intrathecal formation of immune complexes, and production of interferon- α and other inflammatory mediators; clinical sequelae include diffuse NP manifestations such as psychosis and acute confusional states.

SELECTED CLINICAL MANIFESTATIONS OF NEUROPSYCHIATRIC SYSTEMIC LUPUS ERYTHEMATOSUS

Headache

The association between SLE and headache, including migraine, is controversial, with wide variation in the reported prevalence (24% to 72%) in SLE¹ and a high prevalence in the general population (e.g., up to 40% of individuals report having a severe headache at least once per year³). Some investigations, including a meta-analysis of the multiple studies on the issue, found no increase in the prevalence of headache in SLE.⁴ Only one study⁵ reported an association between headache and other clinical features of active lupus. Other potential causes are infection, including aseptic meningitis, and idiosyncratic reactions to medications such as antibiotics and nonsteroidal anti-inflammatory drugs. Thus, although headache may be a component of generalized active SLE in individual patients, it is likely that most headaches in SLE patients, especially those that occur in isolation, are due to non-SLE causes.

Psychosis, mood disorders, and anxiety

Psychosis occurs in up to 8% of SLE patients¹ and is characterized by delusions (false beliefs despite evidence to the contrary) and/or hallucinations (perceptual experiences, typically auditory, that occur in the absence of external stimuli). This rare but dramatic manifestation of NPSLE must be distinguished from psychotic symptoms due to other causes, including high doses of corticosteroids, nonprescription drug abuse, schizophrenia, and depression. In contrast, depression and anxiety occur in 24% to 57% of SLE patients¹ but have no features that are unique to SLE, which leads to uncertainty about the cause and attribution in individual cases. Associations between the presence of anti-P protein antibodies and psychosis or depression in SLE are supported by some but not all studies.^{6,7}

Cerebrovascular disease

The many forms of cerebrovascular disease occur in 5% to 18% of SLE patients,¹ and the cause is likely multifactorial. Coronary heart disease is 5 to 10 times more frequent in SLE patients than in control populations even after adjustment for traditional cardiovascular risk factors.⁸ Accelerated atherosclerosis also contributes to the increased rate of cerebrovascular events in SLE. The prothrombotic state caused by antiphospholipid antibodies provides a rationale for therapeutic intervention with anticoagulants in selected cases.

Seizures

Generalized and focal seizures occur in 6% to 51%¹ of SLE patients. These may occur with active generalized multisystem lupus or as isolated neurologic events and sometimes in association with antiphospholipid antibodies, which co-occur with microangiopathy, arterial thrombosis, and cerebral infarction.

Demyelination, transverse myelopathy, and chorea

Demyelination, transverse myelopathy, and chorea are rare manifestations of SLE that occur in no more than 1% to 3% of patients.¹ Clinical and neuroimaging evidence of demyelination is frequently indistinguishable from signs of multiple sclerosis and may represent concordance of these two

TABLE 135.1

Neuropsychiatric syndromes in systemic lupus erythematosus as defined using the American College of Rheumatology nomenclature

Central nervous system	Peripheral nervous system
Aseptic meningitis	Guillain-Barré syndrome
Cerebrovascular disease	Autonomic neuropathy
Demyelinating syndrome	Mononeuropathy
Headache	Myasthenia gravis
Movement disorder	Cranial neuropathy
Myelopathy	Plexopathy
Seizure disorder	Polyneuropathy
Acute confusional state	
Anxiety disorder	
Cognitive dysfunction	
Mood disorder	
Psychosis

Fig. 135.1 Factors contributing to neuropsychiatric (NP) events in patients with systemic lupus erythematosus (SLE). Focal and diffuse nervous system events may result from direct autoimmune/inflammatory mechanisms related to SLE (primary NPSLE), as a consequence of complications of the disease (e.g., hypertension) or its treatment (e.g., infection) (secondary NPSLE), or as a concurrent non-SLE-related NP event. (Adapted from Hanly JG. *Neuropsychiatric lupus*. *Curr Rheumatol Rep* 2001;3:205-12.)

autoimmune conditions. Transverse myelopathy and chorea⁹ present acutely and are frequently associated with the presence of autoantibodies. Neuro-myelitis optica, also known as *Devic's disease*, is a severe demyelinating disorder that causes longitudinal transverse myelitis of at least three vertebral segments and recurrent optic neuritis. Devic's disease has been reported in patients with SLE and is associated with neuromyelitis optica autoantibodies whose antigenic target is aquaporin-4. Arterial thrombosis due to antiphospholipid antibodies is likely another contributory mechanism in transverse myelopathy. The cause of chorea is less clear, but it may be a consequence of a direct interaction of antiphospholipid antibodies with neuronal structures in the basal ganglia.

Neuropathy and myasthenia gravis

Sensorimotor neuropathy is the most common neuropathy and has been reported in up to 28%¹ of SLE patients, frequently occurring independent of other disease characteristics. These abnormalities are persistent but are

Fig. 135.2 Autoimmune pathogenic mechanisms for neuropsychiatric events attributed to systemic lupus erythematosus (NPSLE). These mechanisms include (1) vascular injury involving both large- and small-caliber vessels mediated by antiphospholipid antibodies (aPL), immune complexes, and leukoagglutination; this results in focal NP events such as stroke and in diffuse NP events such as cognitive dysfunction; (2) injury due to inflammation in which increased permeability of the blood-brain barrier (BBB), formation of immune complexes, and production of interferon- α and other inflammatory mediators leads to diffuse NP manifestations such as psychosis and acute confusional states. MMPs, matrix metalloproteinases; NP, neuropsychiatric; pDCs, plasmacytoid dendritic cells; SLE, systemic lupus erythematosus.

often stable over several years.¹⁰ Other less frequent forms of neuropathy include cranial neuropathy, autonomic neuropathy, plexopathy, mononeuritis multiplex and Guillain-Barré syndrome. Myasthenia gravis has been reported only rarely.

Acute confusional state

The term *acute confusional state* has replaced *organic brain syndrome* and is synonymous with *encephalopathy* and *delirium*. It encompasses a state of impaired consciousness or level of arousal that can progress to coma. Characteristics include fluctuation in arousal or attention, disturbed mood, and impaired cognition. It has been reported in 4% to 7% of SLE patients,¹ and other disorders such as metabolic abnormalities and hypertensive encephalopathy should be considered as potential alternative causes.

Cognitive dysfunction

Cognition includes reception of external stimuli, information processing, learning, storage, and expression. Disturbance in any of these can result in disruption of normal thought and present as cognitive dysfunction. Clinically overt NPSLE events such as stroke are associated with cognitive dysfunction, as is the presence of antiphospholipid antibodies.¹¹ Thus it is not surprising that cognitive dysfunction is more common in patients with past or current clinically overt NPSLE than in those with no such history. Most cross-sectional studies have detected no association between the presence of cognitive impairment and either active systemic disease or the use or dosage of corticosteroids in patients with SLE. No single pattern of SLE-associated cognitive dysfunction has been found, but commonly identified abnormalities include overall cognitive slowing, decreased attention, impaired working memory, and executive dysfunction (e.g., difficulty with multitasking, organization, and planning). Although cognitive impairment may be viewed as a distinct subset of NPSLE it can also serve as a surrogate of overall brain health that may be affected by a variety of factors, including other NP syndromes.

No simple screening test for cognitive dysfunction in SLE patients is currently available because most lack sensitivity in detecting mild but clinically significant dysfunction. Self-report instruments to screen for cognitive difficulties have been validated by some studies^{12,13} but not others.¹⁴ Computerized testing has the potential to facilitate efficient screening of SLE patients by nonexperts,¹⁵ but formal testing remains the only definitive way to diagnose cognitive impairment, and appropriate patients should be

referred for a neuropsychological assessment. The ACR proposed battery of neuropsychological tests for the assessment of cognitive function in SLE² is comprehensive, but its widespread use remains limited because such test batteries are time consuming to administer, require specialized training, and are subject to practice effects with repeated use.

Cognitive dysfunction, as identified by formal neuropsychological assessment, may be subclinical¹⁶ and has been reported in up to 80% of SLE patients,¹ although most studies report a prevalence ranging between 17% and 66%.^{16,17} Longitudinal studies have generally identified stable test performance with persistent or emergent cognitive dysfunction seen in the minority of patients.^{18,19} Several non-SLE causes of cognitive dysfunction may also be present in lupus patients, including sleep deprivation, mood disorders, fatigue, and medication use. Whether these are the sole or contributing causes of cognitive dysfunction in individual patients requires careful consideration.

DIAGNOSIS OF NEUROPSYCHIATRIC SYSTEMIC LUPUS ERYTHEMATOSUS

The first step in the management of a patient with SLE who experiences an NP event is to determine whether the event can be convincingly attributed to SLE rather than considered a complication of the disease or its therapy or whether it reflects a coincidental disease process. In the absence of a diagnostic standard for most of the NP manifestations of SLE this determination is made largely by a process of exclusion. Thus the diagnosis is derived from a careful analysis of the clinical, laboratory, and imaging data on a case-by-case basis. Each source of information may be used to a varying extent, depending on the clinical circumstances (Table 135.2). Examination of the cerebrospinal fluid (CSF) should be used primarily to exclude infection. Measurement of CSF autoantibodies, cytokines, and biomarkers of neurologic damage is still a subject of research. Of the circulating autoantibodies, antiphospholipid antibodies are likely to provide the greatest diagnostic yield. The value of measuring anti-P protein antibodies remains uncertain given the conflicting findings to date. The role of anti-NR2 antibodies in NPSLE is currently unknown, but the most convincing evidence of a clinical-serologic association has emerged from a limited number of studies examining CSF autoantibodies in SLE patients. Electroencephalography and nerve conduction studies are used to investigate seizure disorders and peripheral neuropathy, respectively. Neuropsychologic testing should be conducted to address specific concerns about cognitive ability, because the clinical significance of detecting isolated subclinical deficits is not generally clear. Both standard and more advanced structural neuroimaging may help to determine the attribution of an NP event to SLE, and as more information accumulates, functional brain imaging may also prove useful.

Neuroimaging

One of the most significant contributions of neuroimaging in SLE is in determining the cause of central nervous system (CNS) manifestations.²⁰ A second key contribution is in distinguishing acute and possibly reversible

CNS changes from chronic or irreversible ones. Currently, a variety of magnetic resonance–based imaging methods are available, including standard structural magnetic resonance imaging (MRI), magnetization transfer imaging (MTI), diffusion-tensor imaging (DTI), magnetic resonance spectroscopy (MRS), and functional MRI (fMRI).

Structural MRI is routinely used to determine the appearance and integrity of white matter and gray matter²¹ and to detect global and regional cerebral atrophy. All have been documented in SLE²² and are associated with a variety of clinical outcomes, including cognitive dysfunction.²⁰ However, a limitation of conventional structural MRI is its poor specificity with respect to the underlying pathologic process. In addition, correlations between structural changes and NP manifestations of SLE are low, which makes structural MRI a poor marker for disease progression or treatment outcomes.²¹

The sensitivity and specificity of conventional imaging may be improved with the addition of more advanced methods such as MTI, DTI, MRS, and fMRI.²⁰ MTI measures magnetization transfer between bound and unbound hydrogen molecules (e.g., between white matter and CSF). The transfer is diminished by either decreased bound molecules (e.g., demyelination) or increased unbound molecules (e.g., edema). Decreased whole-brain magnetization transfer on MTI has been reported in SLE patients even in the absence of other structural MRI changes,²³ and tends to be more pronounced in patients with longstanding NPSLE than in patients with active or acute disease.²⁰ DTI provides information about the integrity of white matter tracts by measuring the degree of anisotropy of water diffusion. This can be used in addition to conventional MRI to detect subclinical and/or diffuse white matter damage.²⁰ MRS measures biochemical compounds, including *N*-acetylaspartate (NAA), choline, and creatine, within predetermined regions of interest. Decreased NAA, believed to reflect neuronal/axonal loss or dysfunction, has been reported in SLE patients, even in the absence of visible damage on structural MRI. Decreased NAA has also been associated with other pathologic CNS conditions, such as vasculitis and antiphospholipid syndrome (APS). Whereas MRS examines biochemical changes in brain tissues, fMRI measures changes in local brain deoxyhemoglobin levels that likely reflect neuronal activity, thereby providing an indirect measure of brain function. Thus fMRI may be informative regarding dysfunction or redistribution of functions as a result of SLE.²⁰ Despite its limitations, however, structural MRI remains the neuroimaging method routinely used in clinical practice, because more advanced methods like MTI, DTI, MRS, and fMRI are troubled by variability in results among scanners and a lack of normative or standardized guidelines for interpretation. In the future, however, multimodal imaging is likely to become the standard of practice in the diagnosis and monitoring of neurologic disorders, including NPSLE.

TREATMENT OF NEUROPSYCHIATRIC EVENTS IN SYSTEMIC LUPUS ERYTHEMATOSUS

Before initiation of treatment for any NP event in individual SLE patients it is important to determine as accurately as possible whether the event can be attributed to SLE or to an alternative cause (Table 135.3). In some patients both SLE and non-SLE factors may be contributing. Thus a first step is to identify and treat conditions such as hypertension, infection, and metabolic abnormalities. Symptomatic therapies such as antiepileptic drugs, anxiolytics, and antidepressants also should be used when appropriate. For example, treatment of even mild anxiety and depression may improve cognitive complaints and/or function. The selection of more specific treatment for NP events for which SLE is felt to be the sole or most significant contributing factor is guided by which immunopathogenic mechanism is predominant and must be tailored to the individual patient's needs despite a paucity of controlled studies to guide treatment decisions.

Inflammation-mediated injury

Immunosuppressive therapy with high-dose corticosteroids, azathioprine, and cyclophosphamide is used to varying degrees. With the exception of one study involving 10 patients²⁴ there are no placebo-controlled studies examining the benefit of either oral or intravenous corticosteroids in NPSLE. Similarly, pulse intravenous cyclophosphamide therapy, akin to that used in the treatment of lupus nephritis, has been reported to be beneficial in NPSLE, although only one controlled study has been performed. An open-label study involving 13 patients with lupus psychosis reported a favorable outcome in all patients treated with oral cyclophosphamide for 6 months followed by maintenance therapy with azathioprine.²⁵ A study by Barile-Fabris and colleagues²⁶ compared intermittent intravenous

cyclophosphamide with intravenous methylprednisone administered for up to 2 years to SLE patients with predominantly neurologic disease. They reported a significantly better response rate with cyclophosphamide (95%) than with methylprednisone (54%) ($P < .03$). In virtually all studies, immunosuppressive therapy was used in conjunction with corticosteroids and in addition to symptomatic therapies, such as antipsychotic medications. More targeted immunosuppressive therapies—for example, B lymphocyte depletion with anti-CD20 used alone or in combination with cyclophosphamide²⁷—are promising but require further study.

Vascular injury

Anticoagulation is strongly indicated for focal disease when antiphospholipid antibodies are implicated, and such therapy will usually be lifelong.¹ Because there are no controlled studies to provide guidance on the optimal intensity of anticoagulation required to treat NPSLE caused by thrombosis, one must rely on studies related to prevention of recurrent thrombosis at any anatomic location in patients with APS. Two controlled studies in APS patients found no significant difference between low-intensity warfarin treatment (target international normalized ratio [INR] of 2.0 to 3.0) and high-intensity treatment (target INR of more than 3.0) in the prevention of recurrent thrombosis.^{28,29} However, a minority of patients had arterial thrombosis, and controversy continues on the optimal target INR for the management of such patients.³⁰ Potential adjunctive therapies to consider, especially for patients who experience recurrent thrombosis while receiving warfarin, are antiplatelet agents, antimalarials,³¹ and statins.³²

Treatment of cognitive impairment

The presence, characteristics, and severity of cognitive impairment should first be confirmed by formal neuropsychological assessment. Two approaches, pharmacologic treatment and cognitive rehabilitation, can be considered, although neither has yet been studied systematically in SLE, let alone shown confirmed evidence of efficacy. Only one placebo-controlled study of pharmacologic therapy for SLE-associated cognitive dysfunction has been performed.²⁴ Ten SLE patients who were not currently using corticosteroids were enrolled in a double-blind, controlled trial in which 0.5 mg/kg prednisone was administered daily. Except for complaints related to cognition, these patients presumably had inactive SLE at enrollment. The authors reported improvement in cognition in five of the eight subjects who completed the trial. Although the use of antiplatelet or anticoagulant therapy for the treatment of cognitive dysfunction in SLE patients who have antiphospholipid antibodies but no evidence of thromboembolic phenomena has a theoretical basis, this approach lacks evidence of efficacy and

remains controversial. A single-center, controlled study of treatment with memantine over 12 weeks aimed at “cognitive enhancement” did not demonstrate significant benefit compared with placebo.³³ Variability in the presence and persistence of cognitive deficits in SLE patients as well as the lack of a biologically plausible mechanism for treatment efficacy remain major hurdles in the design of clinical trials examining therapies for SLE-associated cognitive dysfunction.

Cognitive rehabilitation strategies

The cognitive rehabilitation literature provides a taxonomy of theoretical approaches that include the cognitive retraining approach, the holistic approach, and the multicontext approach.³⁴ The cognitive retraining approach is based on the premise that repeated practice and stimulation of an impaired cognitive skill via drill-type exercises of increasing difficulty facilitate “mental muscle building.” Currently, this is the basis of many computerized rehabilitation programs. Some studies have demonstrated improved neuropsychological test performance using this approach,³⁵ although such improvements have not been associated with positive changes in daily functioning.³⁴ Other criticisms include failure to address psychological difficulties that often co-occur with cognitive dysfunction³⁴ and a focus on eliminating cognitive “impairment” rather than minimizing “disability.”

The holistic approach is “a theory-based programme of integrated didactic, experiential, procedural and psychosocial training activities, conducted to restore cognitively compromised adaptation, including decrements in interpersonal and vocational participation, self-awareness and self-determination.”³⁶ Patients are involved in setting their own personalized functional goals, which dictate the content of the program.³⁴ Cognitive strategies are introduced didactically and are then applied in real-life training exercises during and between sessions. In its purest form, this approach involves a lengthy multidisciplinary program (e.g., 5 to 8 hours of treatment per day, 4 to 5 days per week, with 400 to 1200 total contact hours), but modified holistic models that are less intense and more flexible with regard to scheduling are more commonly implemented in practice.³⁶ No studies have been published examining the use of this method in SLE patients, although evidence of effectiveness in studies of other neurologic populations provides some promise of efficacy.

Like the holistic approach, the multicontext approach emphasizes generalizability of training from the therapeutic environment to real-life situations by emphasizing practice and application of cognitive strategies within multiple environments. Concurrently, patients are taught to recognize situations in which a particular strategy may or may not be helpful. Transfer of skills from one situation to the next is facilitated by setting up a predetermined level of success that must be achieved before the skills are applied in a different situation. Unlike the holistic approach, however, this method does not typically include psychosocial interventions. Harrison and colleagues³⁷ have explored the feasibility and effectiveness of using multicontext rehabilitation strategies in SLE patients in an uncontrolled, nonrandomized study. They enrolled 17 women with SLE between the ages of 25 and 60 who reported cognitive difficulties that either interfered with adaptive functioning or caused emotional distress. All completed the MINDFUL program (Mastering the Intellectual Navigation of Daily Functioning and Undoing the Limitations of Lupus), which involved eight weekly 2-hour “psychoeducational group intervention” sessions that focused on cognitive strategy training applied across multiple real-life situations. In addition, the MINDFUL program included a psychosocial support component. The feasibility of this approach in the SLE population was demonstrated by the 100% retention rate. Patients reported better affect and overall quality of life as well as memory self-efficacy, which has been linked to cognitive performance in daily life. Nonetheless, controlled studies are still required to delineate the therapeutic components of such intervention, as well as factors that may interfere with improvement when they are applied to SLE patients with cognitive impairments. In the absence of data on cognitive rehabilitation efficacy some suggestions still seem reasonable. Collaborative, outcome-based goal setting with a focus on disability reduction should be the first step of any rehabilitation program. Combining cognitive retraining with compensatory strategies has the greatest chance of success, especially if there is transfer of skills learned in the clinic to real-life situations. Since most patients have multiple interrelated problems, a multidisciplinary approach to rehabilitation may be best.

Systemic lupus erythematosus:
treatment—renal involvement

■ GEORGE BERTSIAS ■ ANTONIOS C. FANOURIAKIS ■ DIMITRIOS T. BOUMPAS

- Urinalysis is the single most useful test to monitor for renal involvement and relapses after response to treatment.
- Evidence-based recommendations have been developed for the management of lupus nephritis.
- Patients with mild proliferative disease may benefit from glucocorticoids in combination with azathioprine.
- Combinations of mycophenolic acid and moderate to high dosages of glucocorticoids are recommended for induction and maintenance treatment in most patients with moderately severe class III-IV lupus nephritis. Low-dose intravenous cyclophosphamide is an alternative option in white patients.
- In severe proliferative nephritis with acute renal impairment or substantial crescents or necrosis in the biopsy specimen, best available evidence supports the use of combined pulses of intravenous methylprednisolone and high-dose cyclophosphamide as induction treatment. Extended courses of pulse cyclophosphamide or mycophenolic acid may be used for maintenance treatment.
- Patients with pure membranous disease may benefit from glucocorticoids alone or in combination with mycophenolic acid, cyclosporine, or cyclophosphamide.
- One third to one fourth of lupus patients with moderate to severe proliferative lupus nephritis experience relapse after achieving partial or complete response. In cases of severe nephritic flare, early reinstitution of immunosuppressive treatment may preserve renal function.
- In lupus nephritis, tight control of blood pressure and dyslipidemia is of paramount importance.

INTRODUCTION

Effective treatment of lupus nephritis depends on recognition of early phases of renal involvement, before scarring, atrophy, and fibrosis occur. However, many forms of lupus renal disease, including severe forms of glomerulonephritis, are asymptomatic and insidiously progressive. The marked heterogeneity among individual patients in terms of pattern and evolution of disease, as well as response to treatment, presents additional challenges. Yet notwithstanding the capricious nature of the disease and its intrinsic complexities and subtleties, nephritis is one of the most gratifying aspects of lupus to treat because the majority of patients respond well and eventually reach remission. Moreover, novel agents have been added in the therapeutic armamentarium for lupus nephritis, offering options in refractory cases and opportunities for individualization of treatment according to disease characteristics and the patient's needs.

DIAGNOSIS AND ASSESSMENT OF
DISEASE ACTIVITY

Clinical presentation

Nearly half of the patients present with asymptomatic urine abnormalities such as hematuria and proteinuria. Nocturia and/or foamy urine are rarely

reported by patients unless they are specifically asked. Persistent glomerular hematuria is common but rarely found without concomitant proteinuria, which is the dominant feature of lupus nephritis.¹ Nephrotic syndrome accounts for an additional 30% to 40% of cases, whereas rapidly progressive glomerulonephritis is less common and accounts for fewer than 10% of the initial presentations. Hypocomplementemia (especially low levels of C3) and anti-DNA antibodies are frequently encountered. Renal involvement usually appears within the first 2 years of lupus, and its frequency decreases significantly after the first 5 years of disease.

The clinical presentation does not always predict the underlying histologic class of nephritis. This is especially true in patients receiving therapy that may modify findings. Patients with mesangial nephritis tend to have low-grade proteinuria (less than 1 g of protein per 24 hours) with hematuria but typically no cellular casts. Patients with membranous glomerulopathy have proteinuria, often at nephrotic range (more than 3 g of protein per 24 hours), but otherwise blunt urine sediments. Serum C3 levels tends to be normal and anti-DNA antibodies, when present, are usually found in low titers. In contrast, patients with proliferative nephritis may have hypertension, nephritic urine sediment with various degrees of proteinuria (often at a nephrotic range), low C3 levels, and typically high titers of anti-DNA antibodies.

In lupus nephritis, proteinuria reflects the extent of involvement of peripheral glomerular capillary loops, and the disorder tends to increase incrementally from mesangial to proliferative to membranous nephropathy. The latter involves all glomerular capillary loops and is typically accompanied by heavy proteinuria. Concomitant podocytopathy may contribute to enhanced urine protein excretion in some patients.

Urinalysis

Urinalysis is an effective method to detect and monitor disease activity in lupus nephritis. Precautions to be considered to ensure the quality of the urine examination include expeditious examination of a fresh, early morning, nonrefrigerated specimen and flagging of specimens from patients at risk of nephritis to improve the chances for a vigilant examination. Hematuria (usually microscopic, rarely macroscopic) with dysmorphic (fragmented or misshapen) cells (Fig. 136.1) indicates inflammatory glomerular or tubulointerstitial disease. Granular and fatty casts reflect proteinuric disease, whereas erythrocyte, leukocyte, and mixed cellular casts reflect nephritic disease. Broad and waxy casts are found in chronic renal failure. In severe proliferative nephritis, urine sediment may contain the full range of cells and casts ("telescopic urine sediment"). Urine sediment abnormalities in active lupus nephritis are typically accompanied by significant proteinuria (more than 0.5 g of protein per 24 hours), although isolated hematuria and/or pyuria appearing in the context of generalized lupus activity, and not explained otherwise, might be an early sign of kidney involvement and dictates diligent follow-up.²

Renal biopsy

The invasive nature of renal biopsy often provokes anxiety among patients, and some physicians may question its use in patients with newly identified lupus who have typical nephritic or nephrotic syndrome considering the current availability of efficacious noncytotoxic immunosuppressive agents. Still, renal biopsy is essential to document the class and severity of renal abnormalities in lupus since neither can be accurately predicted by laboratory tests. Due to the potentially aggressive nature of lupus nephritis, any sign of renal involvement—in particular, reproducible proteinuria of 0.5 g of protein or more per 24 hours, especially with glomerular hematuria—should be an indication for biopsy.³ Clinically relevant biopsy findings are

Fig. 136.1 Urinalysis is the single most useful test to monitor for renal involvement and relapses after remission in lupus patients. Dysmorphic red blood cells are seen in the urine of a patient with active glomerulonephritis and active urine sediment. Note the fragmented red blood cells and the abnormal sizes and shapes of the majority of cells. The cellular cast in the middle of the figure contains red blood cells. (Courtesy Dr. James E. Balow.)

BOX 136.1 ACTIVITY AND CHRONICITY INDICES*

Activity index (lesions are scored 0 to 3 with a maximum score of 24 points)

- Hypercellularity: endocapillary proliferation compromising glomerular capillary loops
- Leukocyte exudation: polymorphonuclear leukocytes in glomeruli
- Karyorrhexis/fibrinoid necrosis (weighted $\times 2$): necrotizing changes in glomeruli
- Cellular crescents (weighted $\times 2$): layers of proliferating epithelial cells and monocytes lining Bowman capsule
- Hyaline deposits: eosinophilic and periodic acid–Schiff–positive materials lining (wire loops) or filling (hyaline thrombi) capillary loops
- Interstitial inflammation: infiltration of leukocytes (predominantly mononuclear cells) among tubules

Chronicity index (lesions are scored 0 to 3 with a maximum score of 12 points)

- Glomerular sclerosis: collapse and fibrosis of capillary tufts
- Fibrous crescents: layers of fibrous tissue lining Bowman capsule
- Tubular atrophy: thickening of tubular basement membranes, tubular epithelial degeneration, with separation of residual tubules
- Interstitial fibrosis: deposition of collagenous connective tissue among tubules

*Scored on a scale of 0 to 3 representing either (a) absent, mild, moderate, and severe lesions or (b) the presence of lesions in none, <25%, 25%–50%, and >50% of glomeruli, respectively.

more frequent in the presence of significant proteinuria,⁴ although biopsy can also be considered in cases of persisting isolated glomerular hematuria, isolated leukocyturia (after other causes, such as infection or drugs, are excluded), or unexplained renal insufficiency with normal urinary findings.

Pathologic renal lesions should be classified according to the revised 2003 International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification system (Table 136.1),⁵ with assessment of active and chronic glomerular, tubulointerstitial, and vascular lesions (Table 136.2 and Box 136.1).⁶ In several studies of lupus nephritis, class IV nephritis has been found to be the most common (approximately 40% of cases), followed by class III and V with approximate frequencies of 25% and 15%, respectively.

Monitoring of lupus nephritis

Renal function

Renal function is commonly assessed by measurements of blood urea nitrogen, serum creatinine (SCr) level, and creatinine clearance. SCr level is relatively insensitive for detection of early changes in glomerular filtration rate (GFR), and its absolute level is influenced by muscle mass and age. In early renal disease, an initial decline in GFR may lead to only a slight increase (0.2 mg/dL or less) in SCr concentration due to increased proximal tubular secretion of creatinine. Consequently, patients with a true GFR of 60 to 80 mL/min may still have an SCr concentration that is approximately 1.0 mg/dL. However, once SCr levels exceed 1.5 to 2.0 mg/dL, changes in SCr level correlate well with changes in the GFR. Assessment of renal

TABLE 136.1

Histologic classification of lupus nephritis according to the International Society of Nephrology/Renal Pathology Society (2003)

Class I	Minimal mesangial lupus nephritis Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence.
Class II	Mesangial proliferative lupus nephritis Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits. A few isolated subepithelial or subendothelial deposits may be visible by immunofluorescence or electron microscopy, but not by light microscopy.
Class III	Focal lupus nephritis Active or inactive focal, segmental, or global endocapillary or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations.
Class IV	Diffuse lupus nephritis Active or inactive diffuse, segmental or global endocapillary or extracapillary glomerulonephritis involving $\geq 50\%$ of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into <i>diffuse segmental</i> (IV-S) lupus nephritis when $\geq 50\%$ of the involved glomeruli have segmental lesions and <i>diffuse global</i> (IV-G) when $\geq 50\%$ of the involved glomeruli have global lesions. <i>Segmental</i> is defined as a glomerular lesion that involves less than half of the glomerular tuft. This class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation.
Class V	Membranous lupus nephritis Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations. Class V nephritis may occur in combination with class III or class IV, in which case both will be diagnosed. Class V nephritis may show advanced sclerotic lesions.
Class VI	Advanced sclerotic lupus nephritis. $\geq 90\%$ of the glomeruli globally sclerosed without residual activity.

TABLE 136.2

Evaluation of renal biopsy specimens in lupus nephritis

Renal biopsy parameters	Evaluation
Assure that sample is adequate	Specimens with <10 glomeruli are suboptimal
Light microscopy stains	<i>Hematoxylin-eosin</i> : best to identify inflammatory cells <i>Trichrome (Masson)</i> : best for interstitial fibrosis, glomerulosclerosis <i>Periodic acid–Schiff (PAS)</i> : identify basement membrane abnormalities
Immunofluorescence studies	Useful for identification of immune deposits
Electron microscopy	Helps to define distribution (subendothelial, epithelial, membranous deposits) of immune complexes
Activity and chronicity indexes	Useful in organizing renal biopsy report as a complement to World Health Organization classification
Important elements to consider	Activity index: crescents, fibrinoid necrosis Chronicity index: interstitial fibrosis, tubular atrophy, glomerular sclerosis

function is most readily achieved by measuring creatinine clearance in 24-hour urine collections; the requisite 24-hour urine collection is cumbersome, and errors in collection may lead to unreliable estimates. Predictive equations to estimate GFR offer a rapid alternative method of evaluating renal function based on SCr concentration and anthropometric data. To this end, the Cockcroft-Gault and Modification of Diet in Renal Disease (MDRD)

equations are widely used in clinical practice, although they both lack accuracy when true GFR is 60 mL/min/1.73 m² or more.⁷

Changes in renal function are more important than absolute values of renal function, and reproducible changes in SCr concentration (20% to 30% increase or more) or GFR (10% or more deterioration from baseline) are of concern because they indicate significant ongoing loss of renal function. Persistently increased SCr levels (2.0 mg/dL or higher) at the time of response to immunosuppressive treatment is associated with positive likelihood ratio of 10.8 for subsequent development of end-stage renal disease (ESRD).⁸ Conversely, reduction of SCr concentration (even within the “normal” range of values) at 6 months after induction therapy is associated with increased likelihood of a favorable long-term renal outcome (odds ratio, 14.9).⁹

Proteinuria

Timed urine collection to calculate 24-hr protein excretion is considered the gold standard, and values are obtained at baseline and before major therapeutic decisions. Collections of urine in which creatinine concentrations deviate significantly from population averages for males (20 mg/kg/day) or females (15 mg/kg/day) should raise suspicions about the adequacy of the urine collection. Spot urine protein-creatinine ratio (UPCR) measured in a first-morning-void urine sample is a valid and conveniently repeatable measure for detecting within-patient changes in proteinuria and is currently recommended for monitoring patients with lupus nephritis.^{3,10} In general, the numeric ratio approaches the number of protein grams per 24 hours of proteinuria (normal UPCR is less than 0.2). Reduction in UPCR to less than 1.0 at 6 months after initiation of immunosuppressive treatment has a positive predictive value of 87% for good long-term outcome (defined as SCr level of less than 1.4 mg/dL),⁹ whereas persistence of a UPCR of more than 0.5 despite immunosuppressive treatment is associated with increased risk (positive likelihood ratio, 5.6) for the development of ESRD.⁸

Urinalysis

Findings of the analysis that examines centrifuged urine for red blood cells, white blood cells, and cellular casts can reflect inflammation in the kidney, but there are few data on the reproducibility of these measures. Resolution of active urine sediment is a feature of renal response but has to be sustained for several months to be clinically meaningful. Reappearance of urine cellular casts has more than 80% sensitivity and specificity for flares (defined as increases in SCr concentration and/or proteinuria) and may precede other signs of flare by several weeks.¹¹

Serologic Testing

Increased anti-DNA antibody titers and low complement (C3/C4) concentrations tend to be associated with increased activity and worse renal outcomes in lupus nephritis. Changes in the concentrations of these markers, rather than their absolute levels, tend to be more valuable clinically. Although serum C3 concentration has generally higher sensitivity than serum C4 concentration (72% to 85% vs. 28% to 74%), both tests have modest specificity for active lupus nephritis.¹² The diagnostic accuracy of serum levels of anti-double-stranded DNA (dsDNA) is also modest, with positive and negative likelihood ratios ranging from 1.5 to 4.8 and 0.3 to 0.8, respectively.³ Other tests such as anti-C1q and antinucleosome antibodies have higher sensitivity and specificity rates for active renal disease, but further validation is required. Lupus patients with either rising anti-DNA antibodies or falling complement levels should be closely monitored for signs of active renal disease, at which point preemptive therapy should be instituted.

Biomarker levels

A number of serum and urine biochemical and molecular biomarkers, including urine levels of the chemokine monocyte chemoattractant protein-1 (MCP-1) and neutrophil gelatinase-associated lipocalin (NGAL) and serum levels of tumor necrosis factor–like weak inducer of apoptosis (TWEAK), have been studied in lupus nephritis.¹³ Most of these results, however, are limited by the short duration of the studies, the inclusion of a relatively small number of patients, and the lack of confirmation by independent investigators. Importantly, none of the biomarkers has been validated in the context of prospective studies as a true surrogate of long-term renal outcome.

Assessment of prognosis and risk stratification

Numerous demographic and clinical variables can affect prognosis in lupus nephritis, and individual patients have unique combinations of such risk factors (Box 136.2). Although individual risk factors are heterogeneous and vary in their overall impact, patients with a greater number of risk factors have a worse prognosis, are less likely to respond to therapy, tend to respond

BOX 136.2 FACTORS GENERALLY ACCEPTED TO BE ASSOCIATED WITH ADVERSE PROGNOSIS AND HIGH RISK OF RENAL PROGRESSION IN LUPUS NEPHRITIS

Demographic: Black race; limited access to health care, males, children

Clinical: Hypertension; severe extrarenal disease affecting major organ; failure to achieve or marked delay (>2 years) in achieving renal remission; multiple flares of lupus nephritis; pregnancy

Laboratory: Nephritic urinary sediment; azotemia; anemia; thrombocytopenia; antiphospholipid antibodies; thrombotic microangiopathy; hypocomplementemia (especially falling levels); high anti-DNA titer (especially rising titers); persistent severe nephrotic syndrome

Histologic: Proliferative glomerulonephritis (World Health Organization class III-IV); mixed membranous (class V) and proliferative (class III-IV) glomerulonephritis; cellular crescents; fibrinoid necrosis; very high activity index (>12); moderate to high chronicity index (>3); combinations of active (cellular crescents) and chronic (interstitial fibrosis) histologic features; extensive subendothelial deposits

Modified from Balow JE, Boumpas DT, Austin HA. Systemic lupus erythematosus and the kidney. In: Lahita RG, editor. Systemic lupus erythematosus. San Diego: Academic Press; 1999, p. 657-85.

more slowly, and thus require more aggressive treatment. Patient characteristics associated with poor outcomes include male gender, low socioeconomic status, azotemia, anemia, dyslipidemia, hypertension, antiphospholipid syndrome, failure to respond to initial immunosuppressive therapy, and occurrence of flares with worsening of renal function.¹⁴⁻²¹ Combinations of severe active disease indicators (crescents and fibrinoid necrosis) and marked chronic changes (moderate to severe tubulointerstitial fibrosis and tubular atrophy) on renal biopsy are particularly ominous. The impact of race on the severity of disease, response to treatment, and final outcome is becoming increasingly apparent.

THERAPEUTIC AGENTS AND CONTROLLED TRIALS IN LUPUS NEPHRITIS

Of all lupus manifestations, nephritis has been most extensively studied in randomized controlled trials. Many of these trials have been plagued by generic problems, including a small number of patients, variable disease duration, diverse racial and socioeconomic backgrounds of patients, and relatively short follow-up times. Because proliferative (class III-IV) lupus nephritis has a higher prevalence and worse prognosis, most trials have involved patients with this type of nephritis.

Glucocorticoids and cytotoxic drugs

Glucocorticoids are effective in inducing a rapid control of lupus nephritis and are included in all treatment regimens. Pulses of intravenous (IV) methylprednisolone (MP) have become a popular part of initial treatment, although no formal studies have examined whether (1) they are more efficacious than daily oral glucocorticoids, or (2) there is a significant difference between the main dosages employed (500 to 1000 mg vs. 1 g/m²). Many clinicians think that IV pulses of corticosteroids are more effective in rapidly evolving glomerulonephritis, and when they are used in combination with moderate doses of daily glucocorticoids, the severity of adverse effects such as cushingoid appearance, acne, and hirsutism may be lessened.

Seminal studies at the National Institutes of Health have established IV cyclophosphamide (CYC) pulse therapy in combination with glucocorticoids as the gold standard for the treatment of severe lupus nephritis. In patients with proliferative lupus nephritis and renal impairment or adverse histologic features such as crescents and fibrinoid necrosis in 25% or more of glomeruli, seven pulses of IV CYC (0.5 to 1 g/m²) and IV MP on consecutive months, followed by quarterly pulses of IV CYC/IV MP for another 2 years, were superior and prevented more relapses than a shorter regimen limited to seven doses (Box 136.3).^{22,23} Follow-up to a total of 11 years provided further documentation of the benefit of combined IV CYC/IV MP pulses in the long-term outcome of lupus nephritis.²⁴ A meta-analysis of RCTs in patients with class IV lupus nephritis concluded that IV CYC plus glucocorticoids reduced the risk for doubling of SCr concentration (relative risk [RR], 0.59; 95% confidence interval [CI], 0.40 to 0.88) compared with

BOX 136.3 NIH PROTOCOL FOR ADMINISTRATION AND MONITORING OF PULSE CYCLOPHOSPHAMIDE THERAPY

- Estimate GFR by standard methods.
- Calculate body surface area (BSA) (m^2):

$$BSA = \sqrt{\text{Height (cm)} \times \text{weight (kg)} / 3600}.$$
- Cyclophosphamide (CYC; Cytoxan) dosing and administration:
 - Initial dose 0.75 g/m^2 (0.5 g/m^2 if GFR is less than one third of expected normal value).
 - Administer CYC in 150 mL normal saline intravenously over 30 to 60 minutes (alternative: equivalent dose of pulse CYC may be taken orally in highly motivated and compliant patients).
- Obtain WBC count at days 10 and 14 after each CYC treatment (patient should delay prednisone dose until after blood samples are drawn to avoid transient corticosteroid-induced leukocytosis).
- Adjust subsequent doses of CYC to maximum dosage of 1.0 g/m^2 to keep nadir WBC count above 1500/mL. If WBC nadir falls below 1500/mL, decrease next dose by 25%.
- Repeat IV CYC pulses monthly (every 3 weeks in extremely aggressive disease) for another 6 months (seven pulses), then quarterly for 1 year after remission is achieved (as indicated by inactive urine sediment, proteinuria of $<1 \text{ g/day}$, normalization of complement levels [and ideally anti-DNA titer], and minimal or no extrarenal lupus activity).
- Protect bladder against CYC-induced hemorrhagic cystitis:
 - Diuresis with 5% dextrose and 0.45% saline (2 L at 250 mL/hr); frequent voiding; continuation of high-dose oral fluids for 24 hours. Patients should return to clinic if they cannot sustain inadequate fluid intake.
 - Consider administration of mesna (each dose is 20% of total CYC dose) intravenously or orally at 0, 2, 4, and 6 hours after CYC dosing. Mesna is especially important to use if sustained diuresis may be difficult to achieve or if pulse CYC is administered in outpatient setting.
 - If difficulty is anticipated in sustaining diuresis (e.g., severe nephrotic syndrome) or voiding (e.g., neurogenic bladder), insert a three-way urinary catheter with continuous bladder flushing with standard antibiotic irrigating solution (e.g., 3 L) or normal saline for 24 hours to minimize risk of hemorrhagic cystitis.
- Antiemetics (usually administered orally):
 - Dexamethasone (10-mg single dose) plus
 - Serotonin receptor antagonists: granisetron 1 mg with CYC dose (usually repeat dose in 12 hours); ondansetron 8 mg three times a day for 1 to 2 days
- Monitor fluid balance during hydration. Induce diuresis if patient develops progressive fluid accumulation.
- Complications of pulse CYC:
 - Expected: nausea and vomiting (central effect of CYC), mostly controlled by serotonin receptor antagonists; transient hair thinning (rarely severe at CYC doses $\leq 1 \text{ g/m}^2$).
 - Common: significant infection diathesis only if leukopenia not carefully controlled; modest increase in herpes zoster (very low risk of dissemination); infertility (male and female); amenorrhea proportional to age of patient during treatment and to cumulative dose of CYC. In females at high risk of persistent amenorrhea, consider using leuprolide 3.75 mg subcutaneously 2 weeks before each dose of CYC.

GFR, glomerular filtration rate; IV, intravenous; NIH, National Institutes of Health; WBC, white blood cell.

glucocorticoids alone, although it had no significant impact on overall mortality (RR, 0.98; 95% CI, 0.53 to 1.82).²⁵ Intermittent pulse IV CYC is as effective as daily oral CYC but has fewer adverse effects, and thus the former has become the preferred approach.²⁶

Treatment with CYC is associated with considerable toxicity, particularly gonadal dysfunction, which is both age and dose dependent. In one series, the rates of amenorrhea after a long course (15 pulses or more) of IV CYC was 17% for women younger than 25 years of age, 43% for those 26 to 30 years of age, and 100% for patients older than 31 years. The respective rates of amenorrhea in patients who received short courses (seven pulses or fewer) of IV CYC were 0%, 12%, and 25%.²⁷ Ovarian protection with depot gonadotrophin-releasing hormone agonists such as leuprolide 3.75 mg (administered as a monthly subcutaneous injection 2 weeks before pulse IV CYC) has been shown to reduce the rates of amenorrhea (5% vs. 30% in untreated individuals), although data are scarce.²⁸ Other potential adverse

effects of CYC are infectious complications (especially herpes zoster), myelotoxicity (with a leukocyte nadir occurring 10 to 14 days after the CYC pulse), and bladder irritation or even malignancy. Forceful diuresis, use of antiemetic agents, dose adjustments to maintain a safe white blood cell count of $1500/\text{mm}^3$, or more, and concomitant use of moderate rather than high doses of glucocorticoids (0.5 mg/kg/day) are important to reduce toxicity.

The Euro-Lupus Nephritis Trial compared lower doses of IV CYC with the standard high-dose regimen in European patients with lupus nephritis, for the most part patients with milder forms of disease (average SCr concentration, 1.2 mg/dL ; average UPCr, 3.0). A less intensive regimen of IV CYC (500 mg every 2 weeks for a total of six doses) followed with azathioprine (AZA) as maintenance treatment had comparable efficacy—but less toxicity—than a short course of high-dose IV CYC (eight pulses) also followed by AZA.²⁹ At 10 years' follow-up, rates of death, sustained doubling of SCr level, and ESRD were comparable in the low-dose and high-dose groups (11% vs. 4%, 14% vs. 11%, and 5% vs. 9%, respectively),³⁰ which suggests that low-dose IV CYC may be a reasonable option for white patients with mild to moderate proliferative lupus nephritis.

Pulses of IV CYC (0.5 to 1 g/m^2 for 6 monthly doses), cyclosporine (CsA) (5 mg/kg/day , then adjusted according to changes in SCr level), and glucocorticoids alone were studied in an RCT involving 42 patients with pure class V lupus nephritis (median GFR, $83 \text{ mL/min/1.73 m}^2$; median UPCr, 5.4).³¹ All patients received alternate-day oral prednisone (1 mg/kg every other day for 8 weeks, then tapered). At 1 year, remission rates were 27% with prednisone, 60% with IV CYC, and 83% with CsA. Relapse rates per 100 patient-months were 2.0 with CsA versus 0.2 with IV CYC. IV CYC and CsA may be equally effective in treating membranous lupus nephritis; with CsA, however, maintenance therapy may be required to prevent relapses.

Azathioprine

The efficacy of AZA in an induction-maintenance regimen was evaluated in a study that compared treatment with AZA (2 mg/kg/day) and pulsed IV MP (three sets of 3 pulses of 1000 mg) with combination therapy using IV CYC (750 mg/m^2 , 13 pulses in 2 years) and oral prednisone in 87 patients with class III-IV lupus nephritis, 56% of whom had estimated GFRs of less than 70 mL/min .³² After a median follow-up of 5.7 years, doubling of SCr concentration and renal relapses were more frequent in the AZA/IV MP than group than in the IV CYC group (16% vs. 4%, and 27% vs. 4%, respectively). Per-protocol repeat biopsies showed that, although both regimens reduced the number of active lesions, progression of chronic lesions was more effectively halted by IV CYC.³³ During the 10-year follow-up, renal relapses were significantly more common in the AZA/IV MP group (hazard risk, 4.5 compared with IV CYC) and sustained doubling of SCr concentration was also more frequent with AZA (16% vs. 8%), although statistical significance was not reached.³⁴ Nonwhite race was an independent predictor for deterioration of renal function irrespective of type of therapy. AZA may therefore be used as induction treatment in milder cases of proliferative lupus nephritis, especially in white patients. A single open-label trial has also reported efficacy of AZA in combination with oral prednisone in pure class V lupus nephritis.³⁵ AZA has been considered a safe and effective option for maintenance of response in lupus, including cases of moderately severe proliferative lupus nephritis initially treated with CYC.^{30,36}

AZA interferes with the *de-novo* synthesis of inosinic acid via feedback inhibition of 6-thiosinosinic acid. AZA is converted into its active metabolites, which accumulate in tissues and are thought to be responsible for many serious toxicities of the drug. This process is inactivated by thiopurine methyltransferase (TPMT). Codominant genetic polymorphism is seen, with 85% to 90% of people exhibiting high TPMT activity and 10% to 15% showing intermediate TPMT activity, differences caused by heterozygosity at the TPMT locus. Approximately 1 in 300 individuals inherits absolute TPMT deficiency as an autosomal recessive trait. Intermediate TPMT activity is predictive for development of severe adverse effects of AZA. However, the utility of polymerase chain reaction testing to identify TPMT polymorphisms before administration of AZA needs to be evaluated in terms of cost effectiveness. Leukopenia and hepatotoxicity may occur. AZA is considered safe during pregnancy, has not been linked to malformations of newborns, and is therefore suitable for pregnant lupus patients requiring treatment.

Mycophenolic acid

Mycophenolic acid (MPA), an immunosuppressive agent, has been tested extensively both as a remission-inducing agent and as maintenance therapy in lupus nephritis. MPA is a reversible inhibitor of the enzyme inosine monophosphate dehydrogenase, a critical rate-limiting enzyme involved in

the *de-novo* synthesis of purines. The drug functions as a relatively selective antimetabolite, inhibiting T- and B-lymphocyte activation. MPA is administered orally as the morfolinoethyl ester (mycophenolate mofetil, or MMF) or as a salt (enteric-coated mycophenolate sodium, or eMPA). Evidence from transplantation medicine and a single RCT in patients with lupus nephritis³⁷ suggest that the two formulations are likely to be equivalent in inducing improvement of lupus nephritis, with a 720-mg dose of eMPA roughly equivalent to a 1-g dose of MMF. Dose-dependent adverse effects include leukopenia, nausea, diarrhea, and infections. Although the target MMF dosage for induction treatment is 3 g/day, dosages higher than 2 g/day may not always be tolerated, mainly due to gastrointestinal complaints.

Induction therapy

A number of RCTs have compared MPA with CYC as induction treatment in lupus nephritis. Initial trials showed equal or even superior efficacy of MPA, but findings were limited by flaws in the design such as low numbers of patients, underrepresentation of severe forms of lupus nephritis, suboptimal drug dosing, and short follow-up. To overcome these issues, the Aspreva Lupus Management Study (ALMS) included 370 patients with active class III-IV (83%) or class V nephritis, with an average SCr concentration of 1.1 mg/dL and UPCR of 4.1.³⁸ Patients were randomly assigned to receive induction treatment with oral prednisone (60 mg/day, tapered) plus either MPA (target MMF dosage 3 g/day) or IV CYC (monthly pulses of 0.5 to 1 g/m²) for 6 months. Although the trial was designed to demonstrate the superiority of MPA over CYC, at the end of the induction phase, response rates did not differ between the two groups (MPA, 56%; CYC, 53%). Notably, only 16 patients (8.6%) in the MPA group and 15 (8.1%) in the CYC group achieved complete renal response (UPCR of 0.5 or less) after 24 weeks. Post-hoc analysis demonstrated that black and Hispanic patients were more likely to respond to MPA than to CYC (60% vs. 39%, respectively).³⁹

A Cochrane database systematic review and meta-analysis of RCTs compared MPA (MMF) with IV CYC as induction therapy in proliferative lupus nephritis and found no significant differences in mortality (RR, 1.02; 95% CI, 0.52 to 1.98), incidence of ESRD (RR, 0.71; 95% CI, 0.27 to 1.84), complete renal response (RR, 1.39; 95% CI, 0.99 to 1.95), and renal relapse (RR, 0.97; 95% CI, 0.39 to 2.44).^{40,41} MPA-treated patients had significantly lower risks of ovarian failure (RR, 0.15; 95% CI, 0.03 to 0.80) and alopecia (RR, 0.22; 95% CI, 0.06 to 0.86) but not of major infection (RR, 1.11; 95% CI, 0.74 to 1.68). Together, evidence for equivalent efficacy of MPA and CYC, coupled with the ease of administration and the more favorable gonadal toxicity profile of the former, have led to the recommendation to use MPA as initial treatment in most cases of class III-IV lupus nephritis.³ However, the long-term (beyond 5 years) benefit of MPA treatment in terms of hard outcomes remains to be determined.

Severe lupus nephritis

Only high-dose IV CYC demonstrated long-term efficacy in an RCT that included cases of severe lupus nephritis with GFR of 25 to 80 mL/min or with crescents or necrosis in 25% or more of glomeruli.²² Post-hoc analysis of the data for 32 ALMS patients with a baseline GFR of less than 30 mL/min/1.73 m² showed similar rates of renal response at 6 months in MPA- and CYC-treated patients.³⁸ In Asian patients with mixed class IV+V nephritis and noninflammatory necrotizing vasculopathy (average SCr concentration, 1.4 to 1.7 mg/dL), complete renal response at 6 months was achieved by 44% of patients treated with MPA (MMF) compared with 0% of patients treated with IV CYC.⁴² Higher rates of renal response at 12 months were seen with MPA than with IV CYC (54% vs. 26%), although more relapses occurred with MPA than with CYC (44% vs. 11%) in a retrospective cohort study in patients with crescentic nephritis.⁴³ These results vary from those reported in a study of 90 patients with class III-IV lupus nephritis who received induction-maintenance treatment with MPA, which found that patients with a baseline GFR of less than 60 mL/min/1.73 m² had significantly lower rates of complete renal response than patients with a baseline GFR above this value at 6 months (31% vs. 6%), 12 months (56% vs. 21%), and 24 months (49% vs. 8%).⁴⁴ Although there is preliminary evidence to suggest that MPA may be efficacious in severe lupus nephritis, further studies with longer follow-up are required. Combination IV CYC/IV MP pulse therapy is still considered by many experts as the treatment of choice in patients with the severest form of lupus nephritis (rapidly progressive glomerulonephritis/crescentic nephritis).

Membranous lupus nephritis

MPA has demonstrated antiproteinuric effects in class V lupus nephritis, but there is lack of large RCTs to formally test its efficacy. A post-hoc analysis of the data for patients with pure class V lupus nephritis and an average UPCR of 5.0 to 5.8 who participated in two RCTs demonstrated comparable

response rates at 6 months in MPA- and CYC-treated patients.⁴⁵ A small randomized study compared MPA (target MMF dosage 1.5 to 2 g/day) with tacrolimus (titrated to a trough blood level of 6 to 8 mg/L), both in combination with oral prednisone, in Chinese patients with class V lupus nephritis and nephrotic syndrome.⁴⁶ At 24 months, response rates were 71% in the MPA group versus 55% in the tacrolimus group. The two groups had similar longitudinal profiles of serum albumin and creatinine levels. Both agents were well tolerated, and no relapse occurred. Therefore MPA could be used as a first-line immunosuppressive agent in patients with class V lupus nephritis and nephrotic-range UPCR, but additional controlled studies are needed to definitively establish use of MPA in these cases.

Maintenance therapy

In an initial trial in 59 lupus patients with severe renal disease (95% black or Hispanic, 78% with class IV disease, average SCr concentration of 1.6 mg/dL) who received initial treatment with glucocorticoids and monthly IV CYC pulses, both MPA and AZA were superior to quarterly IV CYC pulses for subsequent immunosuppression (relapse-free survival rates during 25 to 30 months of follow-up were 78%, 58%, and 4%, respectively).⁴⁷ Two subsequent RCTs compared MPA and AZA for maintenance treatment in lupus nephritis. The MAINTAIN trial included 105 European patients with proliferative lupus nephritis who received initial treatment with glucocorticoids and low-dose IV CYC (six fortnightly pulses of 500 mg).⁴⁸ Based on baseline randomization, AZA (target dosage 2 mg/kg/day) or MPA (target MMF dosage 2 g/day) was given at week 12 to all patients irrespective of their response to induction treatment. Over a 3-year period, the two groups experienced similar results in terms of renal flares (19% with MPA, 25% with AZA) and doubling of SCr level (6% with MPA, 8% with AZA). Repeat renal biopsies at 2 years failed to detect any significant differences between the two drugs.

These results are different from those reported from the ALMS maintenance study.⁴⁹ This trial included 227 patients (44% nonwhite) who showed a clinical response to either MPA or IV CYC during the induction phase.⁵⁰ These patients underwent a second random assignment to receive either MPA (target MMF dosage 2 g/day) or AZA (target dosage 2 mg/kg/day) and were followed for another 3 years. MPA proved superior to AZA in terms of treatment failure (16% vs. 32%) and renal flares (13% vs. 23%). Rate of treatment failure was 11% for sequential use of MPA after IV CYC compared with 21% for continued treatment with MPA after MPA, and 36% for sequential use of AZA after MPA. Infection rates were similar in the MPA- and AZA-treated groups, but withdrawal due to adverse events was more common with AZA. A meta-analysis of the aforementioned trials (n = 371 participants) found that risk of renal relapse was significantly greater with AZA than with MPA (RR, 1.83; 95% CI, 1.24 to 2.71), although there was no difference in incidence of ESRD, doubling of SCr level, or any adverse event except for leukopenia.^{40,41} We think that both agents can be used for maintenance of remission in lupus nephritis based on availability and potential for pregnancy (AZA preferred).

MPA should be continued if the drug was successful as induction treatment, whereas in the most severe cases, we opt for induction with IV CYC followed by long-term maintenance treatment with MPA.

Calcineurin inhibitors

Calcineurin inhibitors, including CsA and tacrolimus, are inhibitors of T-cell-mediated responses, with tacrolimus being about 10 to 100 times more potent. They were initially used in transplantation medicine but have also shown efficacy in lupus nephritis.

Cyclosporine

CsA has been studied for the treatment of both proliferative and membranous lupus nephritis.

In a randomized study, 40 patients with newly diagnosed class III-IV lupus nephritis and mild renal insufficiency were assigned to sequential therapy with either CYC (eight IV pulses for induction, oral pulses for maintenance) or CsA (4 to 5 mg/kg/day for induction, then tapered).⁵¹ During the induction phase (9 months), nearly three out of four patients in each group showed complete or partial response. At the end of the maintenance phase (18 months), the respective numbers showed a trend in favor of CsA (response rates of 95% vs. 52%), which was attributed to higher antiproteinuric potency. Infectious adverse effects were comparable in the two groups, although CsA was associated with transient increases in blood pressure and reductions in GFR. Another study compared CsA with AZA as a maintenance regimen in an RCT involving 69 patients with class IV lupus nephritis and preserved renal function.³⁶ Patients were initially treated with three daily pulses of 1 g IV MP followed by oral prednisone and CYC for

3 months. After this, they were assigned to receive either CsA (4 mg/kg/day for 1 month and then tapered) or AZA (1.5 to 2 mg/kg/day) for at least 2 years. The rate of flares was comparable in the two groups, and there was no difference in proteinuria and blood pressure levels. This suggests that CsA can be an alternative option for maintenance treatment in lupus nephritis patients with preserved renal function when other agents are not available, are contraindicated, or are not tolerated.

In a trial in patients with membranous nephritis, patients were randomly assigned to receive alternate-day prednisone alone or in combination with either IV CYC (six pulses administered every other month) or CsA (5 mg/kg/day, then adjusted).³¹ After 1 year, the cumulative probability of remission was 27% with prednisone alone, 60% with IV CYC, and 83% with CsA. Relapses of nephrotic syndrome occurred significantly more often after completion of CsA treatment than after IV CYC treatment, which suggests that although CsA is effective as induction therapy in class V nephropathy, maintenance treatment (with CsA or another immunosuppressive agent) may be required to prevent relapses. Common adverse events include mild gastrointestinal complaints, hirsutism, gingival hyperplasia, hypertension in more than 20% of patients, and nephrotoxicity, which is reversible after dose adjustment or drug discontinuation. The drug should be avoided in patients with impaired renal function.

Tacrolimus

Tacrolimus has been used as induction and maintenance therapy in lupus nephritis, particularly in Asian patients.^{49,52} Advantages over CsA include a lower incidence of blood pressure elevation, hyperlipidemia, and adverse cosmetic effects; however, nephrotoxicity still occurs. In a 24-week prospective study involving 60 Chinese patients with active lupus nephritis (87% class III-IV), patients were randomly assigned to receive MPA (MMF 1.5 to 2 g/day), tacrolimus (0.08 to 0.10 mg/kg/day), or IV CYC (monthly pulses of 0.5 to 0.75 g/m²), all in combination with oral prednisone (0.8 to 1.0 mg/kg/day, tapered). After 6 months, renal response occurred in 75% of the patients in the MPA and tacrolimus groups, and 60% of the patients in the CYC group ($P = .445$). More infections occurred in those receiving MPA (40%) and CYC (40%) than in those given tacrolimus (15%), whereas hyperglycemia was more frequent with tacrolimus (25% vs. 10% to 15% with MPA and CYC).

A small RCT compared MPA with tacrolimus in Chinese patients with pure class V lupus nephritis and nephrotic syndrome.⁴⁶ Patients received oral prednisone (0.8 mg/kg/day, tapered) and either MPA (target MMF dosage 1.5 to 2 g/day) or tacrolimus (titrated to a trough blood level of 6 to 8 mg/L). At 24 months, complete and partial response rates were 57% versus 11% ($P = .049$) and 14% versus 44% ($P = .197$) in the MPA and tacrolimus groups, respectively. Both agents were well tolerated, and no relapse occurred during the study period.

Biologic agents

Rituximab

Multiple small, uncontrolled studies have reported efficacy of rituximab (anti-CD20 monoclonal antibody) in lupus nephritis, particularly in patients in whom conventional immunosuppressive regimens, including CYC and MMF, have failed. Pooled data from centers in the United Kingdom and Spain reported complete or partial renal response in 67% of 164 lupus nephritis patients treated with rituximab (375 mg/m²/wk for 4 weeks, or 1000 mg/wk for 2 weeks), used in the majority of cases as second-line treatment for refractory or relapsing disease; 76% of these patients also received concomitant CYC or MMF.⁵³ The presence of nephrotic syndrome or renal failure at the time of rituximab administration was a predictor of poor prognosis and nonresponse. In a systematic review of 300 published cases, response criteria were met by 87% of patients with class III nephritis, 76% with class IV nephritis, and 67% with class V nephritis.⁵⁴

The LUNAR study, a randomized, double-blind, phase 3, multicenter trial comparing rituximab with placebo in 144 racially diverse patients with class III-IV lupus nephritis (average SCr concentration, 1.0 mg/dL; average UPCr, 4.0) failed to meet its primary endpoint, however.⁵⁵ Both groups received high-dose glucocorticoids (IV MP 1 g twice followed by oral prednisolone 0.75 mg/kg/day for 16 days, then tapered) and MPA (MMF 3 g/day). By week 52, the two groups did not differ in rates of complete or partial renal response, although there were numerically more responders in the rituximab group (57% vs. 46%). This trial was criticized for its use of high background immunosuppressive treatment, which might have diluted any effect attributable to rituximab. Until more data become available, we believe that rituximab constitutes a valid therapeutic option for patients whose disease is refractory or relapsing⁵⁶ while they are receiving conventional immunosuppressive agents.

Belimumab

Belimumab (anti-BLyS [B-lymphocyte stimulator]) has not been formally tested in lupus nephritis. Among patients who participated in the two phase 3 RCTs leading to drug approval, 20% had a UPCr of more than 0.5 and 6% had a UPCr of 2.0 or higher at baseline.^{57,58} Post-hoc analysis of the data for this subgroup of patients showed a positive trend in favor of belimumab for reduction of renal flares (1.4% in the 10 mg/kg-dose group vs. 2.8% in the placebo group) and reduction of proteinuria at 52 weeks.⁵⁹ A study of BLyS blockade in lupus nephritis, potentially as an add-on treatment in patients with incomplete response or frequent relapses, is reasonable.

Abatacept

Abatacept (CTLA-4-immunoglobulin) blocks CD28 costimulation on T cells and has been shown to halt progression of nephritis in lupus-prone mice, especially when combined with CYC.⁶⁰ An RCT compared two different doses of abatacept against placebo in 298 patients with class III-IV lupus nephritis. All patients received background immunosuppression with MPA (MMF 2 to 3 g/day) and oral prednisone (30 to 60 mg/day, tapered). After 12 months, abatacept treatment failed to increase the rates of complete response (defined as normalization of GFR, UPCr, and urinary sediment) over placebo, although a greater reduction in proteinuria was observed in patients with nephrotic syndrome at baseline.⁶¹ A post-hoc analysis showed that if less stringent outcome criteria were applied, complete response rates would be higher and significant differences (reaching almost 18%) would be noted in favor of abatacept.⁶² Additional clinical studies of the use of abatacept in lupus nephritis are now in progress.

TREATMENT OPTIONS AND RECOMMENDATIONS

Treatment of lupus nephritis depends on the histologic class and severity of disease, patient preferences, and access to medical care. A working classification of the severity of lupus nephritis, although arbitrary, is essential in

TABLE 136.3
Severity of lupus nephritis*

Proliferative disease	
Mild	Class III without severe histologic features (e.g., crescents, fibrinoid necrosis); low chronicity index (≤ 3); normal glomerular filtration rate; nonnephrotic-range proteinuria
Moderately severe	Mild disease as defined above with partial or no response after the initial induction treatment or delayed remission (>12 mo), or Class III nephritis with adverse histologic features or reproducible increase of $\geq 30\%$ in serum creatinine levels, or Class IV nephritis without adverse histologic features
Severe	Moderately severe as defined above but not responding after 6-12 mo of immunosuppressive treatment, or Class III-IV nephritis with impaired renal function and fibrinoid necrosis or crescents in $>25\%$ of glomeruli, or Mixed membranous and proliferative (class V+III-IV) nephritis, or Class III-IV nephritis with high chronicity alone or in combination with high activity (chronicity index > 4 or chronicity index > 3 and activity index > 10), or Rapidly progressive glomerulonephritis (doubling of serum creatinine within 2-3 mo)
Membranous nephropathy	
Mild	Nonnephrotic-range proteinuria with normal renal function
Moderate	Nephrotic-range proteinuria with normal renal function at presentation
Severe	Nephrotic-range proteinuria with impaired renal function at presentation ($\geq 30\%$ increase in serum creatinine level)

*Concomitant treatment with corticosteroids or other immunosuppressive drugs may modify urinary sediment and/or histologic findings and should be taken into consideration.

Fig. 136.2 Focal segmental (class III) lupus glomerulonephritis. In this patient with normal serum creatinine and nonnephrotic-range proteinuria, the absence of severe histologic features, the limited involvement (fewer than 50% of the glomeruli are involved), and the lack of significant chronic changes such as tubular atrophy and interstitial fibrosis suggest a mild disease. (Courtesy Dr. James E. Balow.)

Fig. 136.3 Moderately severe diffuse proliferative (class IV) lupus nephritis. (a) Dramatic decreases in mesangial and endocapillary cellularity produce a lobular appearance of the glomerular tufts and compromise the patency of most capillary loops. (b) Note the presence of darkly staining subendothelial deposits in the electron micrograph, which results in the thickening of the capillary wall. This patient had active urine sediment, normal renal function, and nephrotic-range proteinuria. (Courtesy Dr. James E. Balow.)

Fig. 136.4 (a) In membranous (class V) lupus nephropathy the capillary walls of the glomerular tuft are prominent and widely patent, resembling "stiff" structures with decreased compliance. (b) Electron microscopy reveals glomerular subepithelial (epimembranous) immune complex deposits that have been incorporated into the glomerular basement. The presence of severe nephrotic-range proteinuria despite normal renal function and the absence of significant chronic interstitial changes suggest a moderately severe disease. (Courtesy Dr. James E. Balow.)

discussing treatment recommendations (Table 136.3 and Figs. 136.2 to 136.5). Patient choices are particularly important, with several studies demonstrating unwillingness of patients to opt for the potent regimens containing cytotoxic agents when confronted with the potential adverse effects. Fertility is an especially emotional issue. Patients at high risk of ESRD should be thoughtfully counseled not to risk compromise of both future health and fertility because of renal failure by rejecting effective therapy for lupus nephritis.

Current strategies for management of lupus nephritis include an initial *induction phase* (lasting 3 to 6 months) aimed at substantially decreasing disease activity (or even attaining remission) and a *maintenance phase* in which the primary goal is to maximize the therapeutic effect and consolidate the response. During this later phase, the balance between the benefits of different regimens in avoiding relapses or smoldering disease activity and issues such as drug adverse effects and quality of life become more pressing. Table 136.4, Box 136.4, and Fig. 136.6 summarize treatment recommendations for all types of lupus nephritis that are based on the American College of Rheumatology¹⁰ and European League Against Rheumatism (EULAR)/European Renal Association–European Dialysis and Transplant Association (ERA-EDTA)³ recommendations for the management of lupus nephritis.

PROLIFERATIVE LUPUS NEPHRITIS

Initial (induction) treatment

Mild disease

A trial of prednisone (0.5 to 1.0 mg/kg/day for up to 4 to 6 weeks) with gradual tapering to alternate-day treatment (0.125 to 0.25 mg/kg) if response occurs, along with monitoring for flares, is our preferred approach for the most mild cases. Addition of alternative immunosuppressive therapy (AZA 1 to 2 mg/kg/day), either from the beginning or during tapering of glucocorticoids, may assist in tapering and decrease cumulative glucocorticoid dose. In selected cases, use of three consecutive pulses of IV MP (500 to 750 mg/pulse) may expedite remission and allow the use of lower dosages of oral prednisone (0.5 mg/kg/day). If the patient does not achieve complete response (clearing of cellular casts and proteinuria, normalization of complement levels, and minimal lupus activity) within 3 months, or if nephritis worsens, we consider initiation of MPA or IV CYC. Delay in cytotoxic therapy beyond 3 to 4 months because of a partial response may have a significant adverse impact on the response to cytotoxic therapy (suboptimal response or increased risk of flare).

Moderate disease

MPA in combination with glucocorticoids is recommended as first-line treatment for most patients with moderately severe lupus nephritis based on evidence of equivalent efficacy, more favorable toxicity profile, and easier administration compared with CYC-based regimens. Administration of three consecutive pulses of IV MP (500 to 750 mg/pulse) may allow the use of lower dosages of oral prednisone (0.5 mg/kg/day); higher dosages (up to 1 mg/kg/day) may still be required to control severe extrarenal activity. MPA exerts dose-dependent immunosuppression, and in RCTs, higher response rates were observed with higher average MPA dosages. Accordingly, the target dosage of MPA during the induction phase should be, if tolerated,

Fig. 136.5 High-risk histologic features suggesting a more severe nephritis. (a) Fibrinoid necrosis with karyorrhexis in a patient with class III glomerulonephritis. (b) Cellular crescents with layers of proliferative endothelial cells and monocytes lining a Bowman capsule along with a predominantly mononuclear interstitial infiltrate. (c) Moderate and (d) severe interstitial fibrosis and tubular atrophy. Note the thickening of the tubular basement membranes and tubular epithelial degeneration with separation of residual tubules due to deposition of collagenous connective tissue among tubules. (e) Mixed membranous and proliferative lupus glomerulonephritis. Note the combination of membranous lesions with the characteristic prominent and widely patent capillary walls, typical of membranous nephropathy, along with mesangial and endocapillary cellularity that compromises the patency of the involved capillary loops, typical of proliferative disease. (Courtesy Dr. James E. Balow.)

TABLE 136.4

Recommended treatment of lupus nephritis*

Histologic type/severity	Type of therapy	
	Induction	Maintenance
Proliferative		
Mild	- High-dose glucocorticoids (0.5-1 mg/kg/day for 4-6 wk with gradual tapering to 0.125 mg/kg every other day within 3-4 mo) alone or in combination with AZA (1-2 mg/kg/day) - If no response within 3-6 mo, treat as moderately severe	- Low-dose glucocorticoids (≤ 0.125 mg/kg on alternative days) alone or with AZA (1-2 mg/kg/day) - Consider further gradual tapering at the end of each year of response
Moderate	- MPA (MMF 3 g/day) with glucocorticoids (0.5 mg/kg/day for 4 wk, then taper) for 6 mo. Consider three initial pulses of IV MP (500-750 mg/pulse), or - Pulse IV CYC (3 g over 3 mo) with glucocorticoids as above - If no response within 6-12 mo, treat as severe	- Low-dose glucocorticoids (≤ 0.125 mg/kg on alternative days) with MPA (MMF 2 g/day) for 18-24 mo after initial response; then consider gradual tapering, or - AZA (2 mg/kg/day)
Severe	- Monthly pulses of IV CYC (0.5-1 g/m²) in combination with pulse IV MP for 6 mo. Background glucocorticoids (0.5 mg/kg/day for 4 wk, then taper), or - MPA (MMF 3 g/day) - If no improvement, consider MPA or rituximab	- Low-dose glucocorticoids (≤ 0.125 mg/kg on alternative days) in combination with quarterly pulses of IV CYC for at least 1 yr beyond response, or - MPA (MMF 2 g/day)
Membranous		
Mild	High-dose glucocorticoids alone or in combination with AZA (2 mg/kg/day)	Low-dose glucocorticoids alone or with AZA (1-2 mg/kg/day)
Moderate/severe	- High-dose glucocorticoids in combination with MPA (MMF 3 g/day), or - Bimonthly pulse IV CYC (0.5-1 g/m², six pulses), or - CsA (3-5 mg/kg/day)	- Low-dose glucocorticoids - AZA (2 mg/kg/day) - CsA (3 mg/kg/day) - MPA (MMF 2 g/day)

*See text for dose and further details.

AZA, azathioprine; CsA, cyclosporine A; CYC, cyclophosphamide; IV, intravenous; MMF, mycophenolate mofetil; MP, methylprednisolone; MPA, mycophenolic acid.

MMF 3 g/day (or eMPA 2160 mg/day) given for 6 consecutive months. Dose reduction should be considered in patients with a GFR of less than 30 mL/min. If gastrointestinal complaints develop, reduction of the daily dose, splitting of the total dose into three or four doses per day, or use of eMPA can be attempted. Although a few studies have reported associations between clinical endpoints and MPA pharmacokinetics (drug trough blood levels at 12 hours, or the area under the curve from 0 to 12 hours),^{63,64} further studies

are needed to determine whether MPA therapeutic drug monitoring can improve efficacy in lupus nephritis. Evidence from the EuroLupus Nephritis Trial²⁹ suggests that the low-dose IV CYC regimen (3 g over 3 months) may be a valid alternative for white patients. When neither MPA nor CYC can be used, patients may be given a trial of AZA (2 mg/kg/day) in combination with IV MP pulses, although this regimen is associated with increased risk of relapse.³² Tacrolimus has been efficacious in Asian patients, but additional

BOX 136.4 JOINT EULAR/ERA-EDTA RECOMMENDATIONS FOR THE TREATMENT OF LUPUS NEPHRITIS**Initial (induction) treatment of lupus nephritis**

- For class IIIA or A/C ($\pm$ V) and class IVA or A/C ($\pm$ V) lupus nephritis: consider
 - MPA (target MMF dose 3 g/day [or eMPA at equivalent dose] for 6 months) (evidence A*), or
 - Low-dose IV CYC (3 g over 3 months) (evidence B), in combination with glucocorticoids
- For severe lupus nephritis with adverse clinical or histologic prognostic factors: consider
 - Similar regimens (MPA (evidence B), low-dose IV CYC (evidence C), but also
 - High-dose IV CYC (0.75 to 1 g/m² for 6 months) (evidence A) or,
 - Oral CYC (2 to 2.5 mg/kg/day for 3 months) (evidence B), in combination with glucocorticoids
- For class V lupus nephritis with nephrotic-range proteinuria: consider
 - MPA (target MMF dose 3 g/day [or eMPA at equivalent dose] for 6 months) (evidence B), in combination with glucocorticoids
 - Alternative options, or for nonresponders: high-dose IV CYC (0.75 to 1 g/m² for 6 months) (evidence A), calcineurin inhibitors (cyclosporine, tacrolimus) (evidence B), or rituximab (evidence C)
- For selected cases of class III-IV or class V lupus nephritis without adverse clinical or histologic prognostic factors, or when MPA and CYC are contraindicated, not tolerated, or unavailable, consider
 - AZA (2 mg/kg/day) (evidence B/C)—associated with higher relapse risk (evidence B)

Subsequent (maintenance) treatment of lupus nephritis

- In patients showing improvement after initial treatment: consider either
 - MPA (initial target MMF dose 2 g/day [or eMPA at equivalent dose]) (evidence A), or
 - AZA (2 mg/kg/day) (evidence A), for at least 3 years, in combination with low-dose prednisone (5 to 7.5 mg/day)
- In patients showing response to initial treatment with MPA:
 - Continue with MPA (evidence C),
 - Switch to AZA if pregnancy is contemplated (evidence C)

Treatment of refractory lupus nephritis

- For patients in whom treatment fails either because of lack of effect or adverse events:
 - Switch from MPA to CYC (evidence C), or
 - Switch from CYC to MPA (evidence C), or
 - Switch to or add rituximab (evidence C)

*Evidence was categorized as follows: A, evidence from RCT(s) or long-term follow-up study of outcomes or post-hoc analysis based on the original randomization allocation without concerns for the validity of the evidence; B, as with A but with concerns about the validity of the evidence, evidence from non-randomized controlled studies without major concerns about the validity of the evidence; C, evidence from non-randomized studies but with concerns about the validity of the evidence, or evidence from case-series, or extrapolation from non-SLE literature, or expert opinion.

AZA, azathioprine; CYC, cyclophosphamide; eMPA, enteric-coated mycophenolate sodium; ERA-EDTA, European Renal Association–European Dialysis and Transplant Association; EULAR, European League Against Rheumatism; IV, intravenous; MPA, mycophenolic acid; MMF, mycophenolate mofetil.

evidence from randomized trials is required. Failure to achieve significant improvement after the initial 6 to 12 months of treatment should precipitate decisions about switching to high-dose pulse IV CYC (see later).

Severe disease

Most investigators agree that, in addition to high dosages of prednisone (0.5 to 1.0 mg/kg/day tapered after 4 weeks), cytotoxic drugs must be administered to patients with severe disease, at least during the induction period. Based on evidence from randomized trials,²² we recommend seven monthly pulses of IV CYC (0.75 to 1 g/m²/pulse) in combination with three initial pulses of IV MP (500 to 1000 mg/pulse) at the start that are continued in patients with more severe disease (crescentic nephritis, rapidly progressive glomerulonephritis) at monthly intervals (one pulse per month) for the first 6 to 12 months. Alternative regimens include (1) oral MPA (target MMF dosage 3 g/day unless there is severe renal impairment) for 6 months,⁴³ or (2) oral CYC (2 to 2.5 mg/kg/day) for 3 months, both in combination with high-dose glucocorticoids.

Subsequent (maintenance) treatment**Mild/moderate disease**

Treatment should include low-dose glucocorticoids (7.5 to 15 mg prednisone on alternate days) in combination with either AZA (2 mg/kg/day) or MPA (target dosage 2 g/day; or eMPA 1440 mg/day), although lower dosages have also been efficacious in patients who did not tolerate higher dosages. A meta-analysis of RCTs demonstrated superiority of MPA over AZA as a response-maintaining regimen in proliferative lupus nephritis; however, both agents yielded extremely low rates of doubling of SCr level, ESRD, and death.⁴¹ Based on the results of ALMS, patients who responded to induction treatment with MPA should continue with MPA, since switching to AZA was associated with more treatment failures.⁵⁰ For patients who were initially treated with IV CYC, and considering the cost difference between the two drugs, we would favor the use of AZA in most cases, especially in white patients.⁶⁵ For pregnant patients and those planning pregnancy, AZA is clearly the drug of choice. Calcineurin inhibitors represent an alternative option.³⁶

The optimal duration of maintenance immunosuppression remains unknown, although recent trials have shown that both AZA and MPA are well tolerated over a period of 3 to 4 years. Gradually tapering the dose of immunosuppressive agent and/or switching from MPA to AZA can be attempted after renal response has been maintained for at least 18 to 24 months, since earlier treatment modifications are associated with increased risk of renal flares.⁶⁶⁻⁶⁸

Severe disease

In patients with severe disease, we recommend maintenance treatment with MPA (target MMF dosage 2 g/day) for at least 3 years, based on the results of ALMS, which showed that the lowest rates of treatment failure were seen in patients who received pulses of high-dose IV CYC followed by immunosuppression with MPA.⁵⁰ IV CYC (0.5 to 1 g/m²), pulsed every 3 months until 12 months beyond renal response, may be used in selected cases, such as in patients who had severe nephritic syndrome and reduced GFR or substantial crescents or necrosis in the kidney biopsy specimen at presentation.^{22,23} Microscopic hematuria and nonnephrotic proteinuria may not clear for several months, even when most other clinical parameters have improved. Treating physicians should realize that complete renal response usually occurs at an average of approximately 1.5 to 2 years after treatment.^{23,32} Therefore abandoning pulse IV CYC therapy because of lack of complete response before at least 2 years of treatment have been completed is not justified unless there is suboptimal response (less than 50% reduction in proteinuria) or worsening of the disease (reproducible reduction in GFR or more than 50% increase in proteinuria at the nephrotic range). In selected patients with severe disease, AZA can be used as a maintenance therapy, provided that near-complete response has been achieved.

MEMBRANOUS LUPUS NEPHROPATHY

Lupus membranous (class V) nephropathy with only background mesangial expansion (pure membranous) has a low risk of progression to ESRD (20% at 10 years). Persistent nephrotic-range proteinuria, impaired renal function, and black race have been implicated as high-risk factors.^{21,69} Persistent nephrotic syndrome increases substantially the risk of arteriosclerotic and thromboembolic complications and adversely affects patient survival. Mixed membranous and proliferative histologic type (class V+VI or class V+III) carries a worse prognosis than even pure proliferative disease, and these patients should be treated the same as those with proliferative disease.

Initial (induction) treatment

A post-hoc analysis of the data for patients with pure class V lupus nephritis and nephrotic syndrome who participated in two short-term RCTs demonstrated comparable antiproteinuric effects in MPA- and IV CYC-treated patients.⁴⁵ MPA (target dose 3 g/day for 6 months) in combination with oral prednisone (starting dose 0.5 mg/kg/day) may therefore be considered as initial treatment for these patients. Evidence from randomized trials also suggests treatment with alternate-day prednisone (0.5 to 1.0 mg/kg) for 2 months tapered to 0.25 mg/kg on alternate days within 3 to 4 months with pulse IV CYC every 2 months (especially in severe disease) or CsA (5 mg/kg/day or less) for 1 year.³¹ Tacrolimus has demonstrated efficacy in Asian patients.⁴⁶ The low-dose IV CYC regimen has not been tested in patients with pure class V lupus nephritis.

Patients with nonnephrotic proteinuria (usually a UPCr of less than 2.0) should be treated initially with titrated doses of renin-angiotensin-aldosterone axis (RAAS) blockers and low-dose glucocorticoids. Careful

RECOMMENDATIONS FOR THE TREATMENT OF PROLIFERATIVE AND MEMBRANOUS LUPUS NEPHRITIS

Fig. 136.6 All regimens are administered on a background of glucocorticoids, which includes three consecutive pulses of intravenous methylprednisolone (0.5 to 1 g/pulse), followed by oral prednisone (0.5 mg/kg/day for the first 4 to 6 weeks of induction, and 0.25 mg/kg every other day for maintenance). The National Institutes of Health regimen (seven monthly pulses of intravenous cyclophosphamide 0.5 to 1.0 g/m²) is for high-risk patients (those with impaired renal function, adverse histologic features [crescents, fibrinoid necrosis, chronicity index of more than 3]), and the Euro-Lupus regimen (six fortnightly pulses of intravenous cyclophosphamide 500 mg) is for low- to intermediate-risk white patients. AZA, azathioprine; CNI, calcineurin inhibitors (cyclosporine, tacrolimus); CYC, cyclophosphamide; GC, glucocorticoids; IV, intravenous; MP, methylprednisolone; MPA, mycophenolic acid.

monitoring for progression to nephrotic syndrome or to mixed membranous and proliferative nephropathy is warranted. Addition of an immunosuppressive agent such as AZA, CsA, or MPA may be considered to minimize the cumulative dose of glucocorticoids or in cases of persistent proteinuria (UPCR of more than 1.0).

Subsequent (maintenance) treatment

Maintenance therapy with AZA or lower doses of CsA may help to prevent relapses, although this has not been formally tested. In severe cases, MPA (target MMF dose 2 g/day) may be used for the first 1 to 2 years.

RESPONSE, REMISSION AND RELAPSE

Renal response and refractory nephritis

Defining renal response and relapse has prognostic implications and may assist in therapeutic decisions. The EULAR/ERA-EDTA recommendations defined *partial renal response* as at least 50% reduction in UPCR and normal or near-normal (within 10% if initially abnormal) GFR.³ Partial response should be achieved preferably 6 months and no later than 12 months after initiation of treatment, since this is associated with long-term preservation of renal function.^{8,9,67} The ultimate goal of treatment should be *complete renal response*, defined as a UPCR of less than 0.5 and normal or near-normal (within 10% if initially abnormal) GFR.³ This is based on evidence that in proliferative lupus nephritis, achievement of complete response compared with partial response is associated with lower risk of development of ESRD.^{16,67,70} In some patients a complete response may not be achieved until 1 to 2 years after initiation of immunosuppressive treatment. A sustained complete response lasting at least 3 to 6 months can be considered as a remission but cannot be judged to be a complete remission in the absence of new biopsy findings. Partial response may be an acceptable outcome when all treatment modalities have been exhausted or cannot be used due to the high risk of toxicity.

A significant number of patients have lupus nephritis resistant to standard immunosuppressive treatments. Based on the previous descriptions of outcomes in lupus nephritis, the EULAR/ERA-EDTA recommendations defined *refractory disease* as failure to achieve (1) any reproducible reduction in UPCR during the first 3 to 4 months, or (2) partial renal response after 6 to 12 months, or (3) complete renal response after 1 to 2 years of immunosuppressive treatment.³ There is paucity of data to guide the management of refractory lupus nephritis; in such cases, decisions may be facilitated by repeating renal biopsy. Uncontrolled evidence suggests that for patients who show no response to MPA or CYC, treatment may be switched from MPA to CYC or from CYC to MPA,⁷¹ or rituximab may be given either as add-on treatment or as monotherapy.³⁴ Additional options include calcineurin inhibitors (CsA, tacrolimus),^{72,73} IV immunoglobulin, plasma exchange, or immunoadsorption. Combination treatment with MPA (MMF 2 g/day), tacrolimus (4 mg/day), and glucocorticoids was superior to treatment with IV CYC (six to nine monthly pulses of 1 g/m²) in patients with class V+VI lupus nephritis refractory to previous immunosuppression with CYC or MPA.⁷⁴

Renal relapses

Approximately 30% to 50% of patients with proliferative lupus nephritis experience relapse after showing partial or complete response to therapy.^{8,16,75} The diagnostic workup for patients experiencing nephritis flare is outlined in Table 136.5. Patients may experience nephritic or proteinuric flares, with the former having more adverse impact on renal outcomes.⁷⁶ Nephritic flares consist of a reproducible increase in SCr concentration of 30% or more (or a reduction in GFR by 10% or more) and active urine sediment with an increase in glomerular hematuria by 10 or more red blood cells per high-power field, irrespective of changes in UPCR. Proteinuric flares consist of a reproducible doubling of UPCR to more than 1.0 after complete renal response or a reproducible doubling of UPCR to more than 2.0 after partial response.^{3,76} Patients who show substantial loss of renal function (SCr concentration of more than 2 mg/dL at the time of response), only partial renal response to treatment, and high chronicity and activity indexes on kidney

TABLE 136.5
Diagnostic approach to a patient with nephritis flare

Confirm flare	■ Is there evidence of extrarenal disease activity? ■ Is there evidence of active renal disease (active urine sediment, ↑ SCr, ↑ UPCR, ↑ anti-dsDNA, ↓ C3)?
Exclude other causes of renal dysfunction	■ Dehydration, uncontrolled hypertension, contrast agents, drugs, nonglomerular hematuria
Nephritic or nephritic flare?	■ Nephritic: active urine sediment, ↑ anti-dsDNA, ↓ C3, stable or increased SCr, ± increase in UPCR ■ Nephrotic: increase in UPCR
Mild or severe flare?	■ Mild/moderate: – Stable SCr – Active urine sediment (cellular casts or >10 red blood cells/high-power field) – ↑ UPCR (≤2.0 for mild, >2.0 for moderate) ■ Severe – ↑ SCr ≥30% from baseline – Active urine sediment
Consider renal biopsy if	■ Flare with nephrotic-range proteinuria ■ Nephritic flare if previous biopsy findings showed mesangial or membranous glomerulopathy, to rule out histologic transformation into a more aggressive type ■ Probably no biopsy in a nephritic flare if previous biopsy finding of proliferative glomerulonephritis

dsDNA, double-stranded DNA; SCr, serum creatinine; UPCR, urine protein-creatinine ratio.

biopsy are more likely to progress to ESRD after a nephritic flare.⁸ These observations would seem to argue in support of strategies to minimize the risk of flare in patients with lupus nephritis; however, although preemptive treatment based on a rising anti-dsDNA titer and/or decrease in serum complement levels without additional evidence of clinically active lupus may prevent flares in a few patients, for the most part these flares are mild, and preventing them comes at the expense of overtreating a much larger number of patients.⁷⁷

For severe nephritic flares with reduction in GFR, reinstitution of immunosuppressive treatment with monthly pulses of IV CYC and glucocorticoids is our preferred approach, with MPA considered as an alternative agent. For a proteinuric or a mild nephritic flare, glucocorticoids alone or combined with AZA or MPA can be used. Rituximab has also shown efficacy in the management of proteinuric renal relapses.⁵⁶ Table 136.6 outlines our current approach to the management of renal flares.

COMORBID CONDITIONS

Hypertension

Hypertension is an independent risk factor for progressive renal failure and cardiovascular disease, and it is associated with worse renal outcome in lupus nephritis.^{75,78} Target blood pressure is less than 130/80 mm Hg and less than 125/75 mm Hg in patients with a UPCR of more than 1.0, since this is beneficial in terms of maintaining lower rate of GFR decline. RAAS blockade with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers is the initial treatment of choice to control blood pressure in most patients. These drugs exert antiproteinuric effects and may be more effective than other agents in reducing the development of ESRD by mechanisms not necessarily related to the control of blood pressure. Patients receiving RAAS blockers need close monitoring for hyperkalemia and worsening renal function for several weeks after initiation of therapy. Adequate blood pressure control often requires addition of other classes of antihypertensive agents such as diuretics and calcium channel blockers, which exert modest antiproteinuric effect.

Dyslipidemia and cardiovascular morbidity

Patients with lupus nephritis are at increased risk of cardiovascular disease and demonstrate 2.8- to 10-fold increased rates of acute myocardial infarction. In addition to conventional risk factors such as hypertension, diabetes

TABLE 136.6
Treatment recommendation for renal flares

Recommended	Alternative
Nephritic	
Mild/moderate	
High-dose glucocorticoids (if no remission in 8 wk, treat as severe)	Glucocorticoids with AZA or MPA
Severe	
Monthly pulses of IV CYC (± IV MP)	Glucocorticoids with MPA, rituximab
Proteinuric	
Mild/moderate	
Moderate dose of glucocorticoids	AZA or CNI (CsA, tacrolimus)
Nephrotic	
High-dose glucocorticoids	Glucocorticoids with CNI, MPA, or bimonthly pulses of IV CYC Rituximab

AZA, azathioprine; CNI, calcineurin inhibitors; CsA, cyclosporine A; CYC, cyclophosphamide; IV, intravenous; MP, methylprednisolone; MPA, mycophenolic acid.

mellitus, and dyslipidemia, attributed both to increased inflammatory burden and the concomitant use of glucocorticoids, other metabolic abnormalities such as premature menopause, kidney failure, dysfunctional high-density lipoprotein, oxidized low-density lipoprotein particles, and higher plasma homocysteine levels are also more prevalent.⁷⁹ Aggressive management of dyslipidemia (serum low-density lipoprotein cholesterol levels of 100 mg/dL or less and serum triglyceride levels of less than 150 mg/dL) is recommended, particularly if chronic kidney disease has developed. Statins may reduce the risk of venous thromboembolism, but their potential use in primary or secondary prevention of thrombotic events in high-risk SLE patients (those with nephritic syndrome or antiphospholipid antibodies) is uncertain. A single randomized, placebo-controlled trial assessed the effects of fluvastatin (40 to 80 mg/day) in 33 lupus nephritis patients who had received a renal transplant due to ESRD.⁸⁰ At the time of trial initiation all patients had dyslipidemia and were receiving triple immunosuppressive treatment with a calcineurin inhibitor, AZA, and prednisone. Fluvastatin treatment significantly reduced the levels of low-density lipoprotein cholesterol and total cholesterol, and there was a trend toward increased major cardiac events in the placebo arm compared with the fluvastatin arm. The role of daily aspirin for primary prevention in lupus nephritis patients has not been studied formally, but such prophylaxis is worth considering on an individual basis.

Thrombotic diathesis and renal vasculopathy

Nephrotic syndrome is associated with increased synthesis of clotting factors and loss of fibrinolytic proteins, such as protein S and C, in the urine. Together with antiphospholipid antibodies, they contribute to a thrombophilic diathesis in lupus nephritis. Patients with nephrotic syndrome (especially those with membranous nephropathy) should be informed about the potential for thrombosis (usually deep vein thrombosis, pulmonary embolism, or renal vein thrombosis). Renal vein thrombosis, although it may be asymptomatic, usually manifests itself with flank pain, hematuria, and worsening proteinuria.

The role of microvasculopathy in the progression of renal insufficiency in lupus nephritis is perplexing. Extraglomerular and intraglomerular renal vascular lesions; subintimal eosinophilic deposits that stain with periodic acid-Schiff stain; and intimal hyperplasia are common in lupus, even in the absence of hypertension. Immune complex deposition (with or without necrosis) within arterioles and small arteries is seen frequently in immunofluorescence studies. The hypothesis has been put forward that microthrombi in glomerular capillaries may contribute independently to progression of renal disease, but true microthrombi (thrombotic microangiopathy) are rather rare in the absence of antiphospholipid antibodies.⁸¹ Antiphospholipid syndrome-associated nephropathy, characterized by thrombotic microangiopathy and chronic histologic lesions such as fibrous intimal hyperplasia, organizing thrombi with recanalization, focal cortical atrophy, and fibrous occlusions of arteries and arterioles,⁸² occurs in lupus patients with antiphospholipid antibodies. Antiphospholipid

syndrome–associated nephropathy has been found to be associated with hypertension, higher SCr levels, and interstitial fibrosis. In patients with coexistent histologic features of nephritis, hydroxychloroquine and/or antiplatelet-anticoagulant treatment can be considered along with immunosuppressive therapy and RAAS blockade for control of blood pressure and proteinuria, but there are no controlled studies of this therapy. Patients with antiphospholipid syndrome should receive anticoagulant treatment.⁸³ True thrombotic thrombocytopenic purpura (TTP), defined as TTP when lupus is inactive, or a TTP-like syndrome with thrombotic microangiopathic hemolytic anemia in patients with systemic activity, may develop lupus patients in rare cases; because the prognosis is poor, such patients must be recognized and treated early.

LUPUS NEPHRITIS IN PREGNANCY

Glomerular perfusion increases during pregnancy, which causes a reduction in SCr levels. In women with significant prepregnancy proteinuria (UPCR of 1.0 or more) protein excretion may increase significantly between 18 and 36 weeks of gestation followed by a sharp decrease postpartum. Patients with normal or near-normal GFR (SCr concentration of less than 1.4 mg/dL) at the time of conception have no worsening of renal function provided there is inactive urine sediment and UPCR is less than 0.5 to 1.0. These women also have a high probability of successful pregnancy. Women with a variety of glomerular diseases and increased SCr levels at baseline have a 10% risk of developing ESRD, whereas those with an SCr concentration of more than 2 mg/dL have a 35% risk. These patients also have a higher risk of hypertension, worsening of proteinuria, and premature delivery and fetal intrauterine growth retardation.^{84,85}

Pregnant lupus nephritis patients should be followed by a multidisciplinary team. For patients with stable renal disease, treatment includes hydroxychloroquine, low-dose prednisone, AZA, and CsA. Hydroxychloroquine should be administered particularly if immunosuppressive agents need to be stopped. MPA or CYC should not be used in the last 3 months of pregnancy, and biologic agents should not be used for at least 4 months before conception, depending on the agent. RAAS blockers should not be used at the time of conception if possible, due to their potential teratogenic effect during the first trimester, or they should be switched to other antihypertensive agents such as nifedipine or labetalol as soon as pregnancy is confirmed. Aspirin therapy should be considered to reduce the risk of preeclampsia.⁸⁴ For patients who are receiving anticoagulant treatment or for whom such treatment is planned, low-molecular-weight heparin should be prescribed, since warfarin should not be used during pregnancy.

Falling serum complement levels and increased creatinine and uric acid levels during pregnancy should raise the suspicion of lupus nephritis rather than preeclampsia. In these patients the presence of nephritic urine sediment is strong evidence for lupus nephritis. Close surveillance for renal relapse during the postpartum period is essential. Refractory cases can be treated with IV immunoglobulin, immunoadsorption, and possibly plasma exchange, depending on disease severity.^{84,86}

LUPUS NEPHRITIS IN CHILDREN

Compared with adults, children with lupus have more active disease at diagnosis and during follow-up, have a higher incidence of glomerulonephritis (60% to 80%), and receive higher doses of glucocorticoids and immunosuppressive drugs.^{87,88} Response to treatment does not differ significantly between children and adults. Children have a greater capacity to compensate for glomerular damage by compensatory hypertrophy in the less involved glomeruli and thus to preserve renal function, although in the long term hyperfiltration may assist glomerulosclerosis.

As in adults, the management of lupus nephritis in children and adolescents is divided into the induction and maintenance phases, and the treatment of relapses. In mild cases (class II nephritis or class III nephritis with a low activity index) with normal GFR, normal blood pressure, and non-nephrotic proteinuria, oral glucocorticoids (up to 1 mg/kg/day) may suffice. Initial pulses of IV MP (30 mg/kg/day up to 1 g/day for 3 consecutive days) may allow a lower oral prednisone dosage (0.5 mg/kg/day). In patients with class III nephritis and a high activity index (more than 10 to 12) or class IV disease, pulse therapy with IV MP and IV CYC (0.75 to 1.0 g/m²) or MPA can be considered. The clinical and histologic progression of class III-IV nephritis in 16 children who completed at least 3 years of continuous treatment with IV CYC was reported, and significant improvements in disease activity, GFR, and renal activity index were observed.^{89,90} In a study of 13

adolescent patients with class III lupus nephritis who were initially treated with either IV CYC (seven monthly pulses of 0.5 to 1 g/m²) or MPA (MMF 300 to 900 mg/m²), both in combination with oral prednisone (2 mg/kg/day, tapered), followed by maintenance treatment with MPA, renal response rates were comparable with IV CYC and MPA, both at the end of the induction phase (57% vs. 83%, respectively) and after an average follow-up of 2 to 3 years (71% vs. 67%, respectively).⁹¹ A subset analysis of the ALMS data for 24 patients younger than 18 years of age (average age, 14.8 years) showed that IV CYC and MPA were comparable in inducing response at 6 months.⁹² Sixteen patients were subsequently enrolled in the maintenance phase, randomly assigned to receive either MPA or AZA. During follow-up, one patient treated with MPA (13%) experienced treatment failure compared with five patients treated with AZA (63%), although results did not reach statistical significance due to the small number of patients. Important to note, serious infections occurred in 30% of those receiving MPA and 21% of those treated with CYC.⁹²

In a retrospective study, 20 pediatric patients with severe proliferative lupus nephritis (average GFR, 71 mL/min/1.73 m²; nephrotic-range proteinuria in 80%) received 6 months of induction therapy with pulse IV MP (30 mg/kg, followed by oral prednisone 0.5 to 1.0 mg/kg/day) and IV CYC (0.5 g/m²).⁹³ AZA (2 mg/kg/day) was commenced as a remission-maintaining regimen in all patients; in 10 patients, treatment was subsequently switched to oral MPA (MMF 1200 mg/m²/day) due to intolerance or lack of efficacy. When this approach was followed, 70% showed complete response and another 15% experienced partial response. Combinations of MPA and CsA have also been used for the treatment of severe class III-IV lupus nephritis that did not respond adequately to initial induction treatment.⁹⁴ Together, these results suggest that either IV CYC or MPA may be considered for the initial management of pediatric lupus patients with active proliferative nephritis, including severe forms. For maintenance treatment, either AZA or MPA can be used, with MPA exerting more potent immunosuppression. An alternate-day regimen of oral prednisone 10 to 15 mg should be the aim during the maintenance phase.

Renal flares are an important issue that has not been adequately addressed. An alternative to a second course of IV CYC and glucocorticoids, which may be associated with significant long-term toxicity, is initiation of MPA or a combination of IV methotrexate and CYC. Rituximab (600 mg/m², maximum dose of 1 g/m² on days 1 and 15) has been successful in patients with refractory renal and extrarenal disease and can be used as monotherapy or in combination with CYC.⁹⁵

MANAGEMENT OF CHRONIC RENAL INSUFFICIENCY

As in other chronic glomerulopathies, progressive renal injury in lupus nephritis involves predominantly nonimmune mechanisms. Persistent proteinuria, hypertension, and dyslipidemia are implicated in the deterioration of renal function. Maladaptive compensatory mechanisms (glomerular hypertrophy, increased blood flow, intraglomerular hypertension) working in concert with ongoing immunopathogenic processes culminate in progressive decline of GFR. Based on the guidelines of the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (www.kidney.org/professionals/KDOQI/), efforts should aim to minimize exposure to nephrotoxic drugs and contrast agents, avoid dehydration, correct anemia by the use of erythropoietin to keep hemoglobin concentration at 10 to 11 g/dL, use calcium carbonate (650 mg 1 to 3 times a day) to decrease intestinal absorption of phosphates and ameliorate metabolic acidosis, and restrict protein and salt intake (Table 136.7).

END-STAGE RENAL DISEASE AND DIALYSIS

Approximately 10% to 20% of patients with lupus develop ESRD. Progression of lupus nephritis to the point of dialysis does not necessarily indicate ESRD, and 5% to 10% of patients requiring dialysis eventually recover sufficient renal function to interrupt dialysis temporarily or for long periods. Patients with rapid deterioration of renal function are more likely to have a reversible physiologic (e.g., acute tubular necrosis) or pathologic (e.g., crescentic glomerulonephritis) component. In these patients, immunosuppressive therapy may continue during dialysis (pulse IV MP with pulse IV CYC 0.4 to 0.5 g/m² administered 8 to 10 hours before dialysis). We generally consider discontinuing immunosuppressive treatment in patients with an SCr concentration rising steadily to 5 mg/dL or higher, inactive urine sediment, and contracted renal size, or with renal biopsy results showing class VI disease.

TABLE 136.7
Management of chronic kidney disease in patients with lupus nephritis*

Detecting reversible causes of renal deterioration	
■ Hypovolemia	– Vomiting, diarrhea, diuretic use, fever, sepsis
■ Drugs that lower the GFR	– NSAIDs: especially when administered to patients with hypotension
	– ACE inhibitors/ARBs: especially when administered to patients with bilateral renal artery constriction/mononephros
■ Nephrotoxic drugs	– NSAIDs
	– Radiographic contrast material
	– Antibiotics: mainly aminoglycosides
Preventing or slowing the progression of chronic kidney disease (renoprotection, most important in patients with GFR < 60 mL/min/1.73 m ²)	
■ Blood pressure control (<130/80 mm Hg)	– Sodium restriction
	– ACE inhibitors/ARBs
	– Thiazide diuretics (SCr < 1.8 mg/dL), loop diuretics (SCr > 1.8 mg/dL)
	– β-Blockers
■ Reduction of proteinuria (UPCR < 0.5)	– Moderate protein restriction: ≤0.8 g/kg/day
	– ACE inhibitors/ARBs: titrate to maximum tolerated dose, monitor SCr and potassium
■ Lipid-lowering therapy (LDL-C < 100 mg/dL)	– Statins
■ Cessation of smoking	
Treating the complications of chronic kidney disease (usually in patients with GFR of 15–29 mL/min/1.73 m ²)	
■ Anemia (maintain hemoglobin level of 11–12 g/dL)	– Erythropoietin
	– Iron supplementation when transferrin saturation is <25% and ferritin is <300 μg/mL
■ Hyperkalemia	– Potassium restriction, resin
■ Acidosis (maintain HCO ₃ ⁺ ≥ 22 mmol/L)	– Oral sodium bicarbonate
■ Hyperphosphatemia (target serum PO ₄ [–] 2.7–4.6 mg/dL)	– Phosphorus binders (sevelamer, lanthanum)
■ Hyperparathyroidism (target intact PTH 70–110 pg/mL)	– Active vitamin D (calcitriol, doxercalciferol), cinacalcet
■ Further deterioration of kidney disease	– Scheduled placement of arteriovenous access for hemodialysis or peritoneal catheter

*Based on guidelines of the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (www.kidney.org/professionals/KDOQI/).
ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; GFR, glomerular filtration rate; LDL-C, low-density lipoprotein cholesterol; NSAIDs, nonsteroidal antiinflammatory drugs; PTH, parathyroid hormone; SCr, serum creatinine; UPCR, urine protein-creatinine ratio.

Many lupus patients with advancing renal disease experience a decline in lupus clinical and serologic activity. However, up to 50% of patients receiving maintenance hemodialysis continue to experience lupus activity that can be difficult to distinguish from complications of uremia.^{96,97} Lupus activity is more likely to persist during dialysis when renal failure develops relatively rapidly rather than over a more extended period. Another potential issue in patients receiving hemodialysis is the presence of antiphospholipid antibodies or even antiphospholipid syndrome, which is associated with increased risk of vascular access thrombosis.⁹⁸ Peritoneal dialysis is also an option for lupus patients with ESRD and offers greater independence. Retrospective cohort studies have shown comparable long-term outcomes in patients receiving peritoneal dialysis and those receiving hemodialysis, although the former group had higher maximal disease activity on follow-up.⁹⁹ However, patients receiving peritoneal dialysis may be more likely to experience infectious complications (peritonitis and/or exit-site infections), and hypoalbuminemia and use of immunosuppressive agents are major risk factors.¹⁰⁰ Cardiovascular mortality is increased in lupus patients with ESRD,¹⁰¹ and adherence to the general guidelines for the management of cardiovascular risk factors is recommended.

RENAL TRANSPLANTATION

There are no firm rules for the optimal timing of renal transplantation in lupus nephritis patients. Although some patients with living related donors

TABLE 136.8
Novel approaches to the treatment of proliferative lupus nephritis

Approach	Example
A. Nonspecific immunosuppression	
High-dose immunoablative therapy	High-dose cyclophosphamide with HSCT High-dose cyclophosphamide without HSCT
Kinase inhibitors	Jak inhibitors, Syk inhibitors
B. Biologic response modifiers	
Interference with T-cell costimulation	Anti-CD40 ligand antibody CTLA-4-Ig
B-cell depletion	Anti-CD22 antibodies
B-cell activation	Anti-BLyS antibodies or soluble receptors (TAC-Ig)
Cytokine-directed therapy	Anti-IL-21 antibody Anti-IL-6 receptor antibody Anti-IFN-α antibody
Interference with immune complex formation and deposition	Deoxyribonuclease Anti-idiotypic antibodies and competitive peptides
C. Potential targets	
Complement components	Anti-C5 monoclonal antibody Soluble recombinant complement C3 inhibitor
D. New approach	
Immunosuppression and tissue repair	Mesenchymal stem cell transplantation

BLyS, B-lymphocyte stimulator; HSCT, hematopoietic stem cell transplantation; Ig, immunoglobulin; IL, interleukin; IFN-α, interferon-α.

proceed directly to transplantation without prior dialysis, maintenance on dialysis for a period of at least 3 months may allow some patients to recover adequate function for significant periods of time. Transplantation should be performed when clinical (and ideally, serologic) lupus activity has been absent, or at a low level, for at least 3 to 6 months.¹⁰² Comparative studies suggest that patient and graft survival in lupus patients are generally comparable with those in other patient groups.^{103,104} As in patients with other diseases, outcomes were superior in lupus patients who received living-donor organs and underwent preemptive transplantation.^{99,105} Recurrence of lupus nephritis in the renal allograft is a rare event (2% of cases) and not an important cause of graft loss. Patients with moderate to high titers of antiphospholipid antibodies are at increased risk of thrombotic complications and renal allograft loss, and may receive anticoagulation treatment perioperatively.¹⁰⁶ Low complement levels after renal transplantation in association with proteinuria may be considered a risk factor for recurrence of immune deposits, with a negative impact on graft survival.¹⁰²

FUTURE DIRECTIONS

Novel therapies

There are two major approaches to the development of novel treatments for lupus nephritis (Table 136.8). The first is to modify existing immunosuppressive therapies by changing the dose or duration of commonly used drugs, administering these drugs in combination or sequentially to reduce adverse events, or trying more recently developed drugs that have been effective in other diseases. The other major approach is to target specific steps in the pathogenesis of lupus nephritis, such as interfering with T- and B-cell activation by blocking costimulatory molecules, preventing immune complex formation or deposition, and diverting the autoimmune response by inducing antigen-specific tolerance or by interfering with abnormal cytokine networks. High-dose immunoablative chemotherapy with autologous hematopoietic stem cell transplantation has been applied to treat severe SLE manifestations.¹⁰⁷ Until more data are available, stem cell transplantation remains an experimental procedure that needs to be considered in critically ill lupus patients, ideally performed in centers with experience in both lupus and bone marrow transplantation in the context of formal protocols.

Acknowledgments

The authors would like to acknowledge the contribution of Dr. Prodrimos Sidiropoulos, who was coauthor of this chapter in the previous edition.

Systemic lupus erythematosus in the pregnant patient and neonatal lupus

■ PRATEEK CHAUDHARY ■ MEGAN E.B. CLOWSE

- Disease quiescence in systemic lupus erythematosus (SLE) is an important predictor of pregnancy outcome.
- The presence of antiphospholipid antibodies is associated with an increased risk of maternal thrombosis, recurrent fetal loss, and preeclampsia.
- The presence of anti-Ro/anti-SSA antibodies is associated with neonatal lupus and, in rare cases, fetal congenital heart block.
- Distinguishing lupus nephritis from preeclampsia can be difficult, particularly since the two processes can be superimposed on one another.
- Hydroxychloroquine, low-dose corticosteroids, and azathioprine are considered among the safer medication options in pregnancy.
- Many pregnancies in patients with SLE, if carefully monitored and appropriately treated, result in healthy children.

INTRODUCTION

Systemic lupus erythematosus (SLE) is a rheumatic illness that often affects young women of reproductive age. Pregnancy in the setting of SLE is frequently encountered and can sometimes create management challenges, particularly in women with active disease at the time of conception, a history of organ damage (such as lupus nephritis), and antiphospholipid and/or anti-Ro/anti-La antibodies. Although women with lupus tend to have fewer live births compared with the general population, the vast majority of pregnancies in the setting of SLE are uneventful and result in normal maternal and fetal outcomes. With the advent of effective therapies and an increased understanding of rheumatic diseases, the pregnancy loss rate in SLE has improved dramatically over the years to approximately 17% today.¹

PREPREGNANCY EVALUATION AND COUNSELING

Although the presence of SLE does not have a detrimental impact on fertility, active lupus at the time of conception is a predictor of a negative pregnancy outcome. Disease quiescence at the time of, and 6 months previous to, conception is an important prognostic factor for pregnancy loss and preterm delivery.² The presence of active lupus nephritis is a predictor of increased lupus activity during pregnancy and poor pregnancy outcomes.³ Pregnancy planning should certainly be part of the initial and ongoing evaluation in women of childbearing age, and proper contraception should be used if necessary, particularly in women who are sexually active and taking high-risk medications. The use of emergency contraception should also be discussed with the patient.

Major concerns are the mother's health (including her ability to be a mother to the child), the willingness to risk delivery of a preterm infant, specific risks caused by the presence of antiphospholipid and/or anti-Ro (anti-SSA)/anti-La (anti-SSB) antibodies, and the use of certain medications during pregnancy. There does not appear to be a detrimental impact on a

mother with lupus or on the fetus when *in-vitro* fertilization and other reproductive technologies are used.

Women with SLE who desire to become pregnant should be asked about their pregnancy history, including complications encountered during previous pregnancies, modes of delivery, and fetal outcomes. In women with a history of SLE-related organ damage, such as lupus nephritis and hemolytic anemia, SLE should be quiescent for at least 6 months before conception. Women with severe lung disease (e.g., interstitial lung disease), heart disease (e.g., recent myocardial infarction), or cerebrovascular accident should be advised to avoid pregnancy altogether and perhaps to explore alternatives to childbirth such as surrogacy or adoption.⁴⁻⁶ The reason is the high risk of mortality associated with these complications. Severe pulmonary hypertension, for instance, has a risk of mortality in pregnancy that approaches 30%.

Two serologic markers, antiphospholipid antibodies and anti-Ro/anti-La antibodies, also indicate higher risk of pregnancy complications. The presence of antiphospholipid antibodies is associated with maternal thrombosis, recurrent fetal loss, and an increased risk of preeclampsia.^{7,8} The presence of anti-Ro and anti-La antibodies is associated with fetal heart block and, in some cases, the need for a permanent pacemaker.^{9,10} Box 137.1 is an overview of potential risk factors for pregnancy complications in women with SLE.

MEDICATION USE IN PREGNANCY

Although there are very few clinical trials addressing the safety of medications in pregnancy, clinical experience, anecdotal evidence, and consensus conferences have attempted to address the safety of medications in pregnancy and lactation (Table 137.1; also see Chapter 68).

Hydroxychloroquine not only is generally regarded as safe to use in pregnancy but also is associated with decreased SLE flares when used continuously.¹¹ Unless there is a clear contraindication, treatment with hydroxychloroquine should not be interrupted in the setting of pregnancy.

Nonsteroidal antiinflammatory drugs can be used sporadically in the first and second trimesters of pregnancy, but they are associated with an increased risk of miscarriage and oligohydramnios in the first and second trimesters, respectively. Nonsteroidal antiinflammatory drugs should be avoided altogether in the last trimester of pregnancy due to concerns of premature closure of the ductus arteriosus and worsening of hypertension.

Corticosteroids are sometimes indicated in the setting of a lupus flare. It is important to know which steroids cross the placenta, and therefore affect the fetus, and which ones do not. Dexamethasone and betamethasone cross the placenta and should not be used unless there is an intent to expose the fetus to corticosteroids. Prednisone and prednisolone are deactivated by placental hydroxylases but should be used with caution given the increased risk of maternal diabetes, hypertension, preeclampsia, and premature rupture of membranes. Oral prednisone should not be used prophylactically and, if the drug is necessary, should be given at the lowest possible dose needed to control symptoms.

Antihypertensives may be required in the management of SLE patients. Angiotensin-converting enzyme inhibitors are contraindicated in the setting of pregnancy; methyldopa, nifedipine, and labetalol are generally thought to be safe options.

The impact of therapies affecting B cells, such as rituximab and belimumab, is largely unknown, and these drugs are not recommended in pregnancy. Although many normal pregnancy outcomes have been reported in

patients taking rituximab, there have been reports of preterm birth, infections, hematologic abnormalities, and even death associated with inadvertent rituximab exposure in pregnancy. Avoidance of pregnancy for at least 12 months following rituximab exposure should be strongly considered.¹²

Azathioprine is probably the safest immunosuppressive medication in pregnancy, and although its use has been associated with lower birth weights and prematurity in small human studies, it has been widely used in pregnant SLE patients without any negative sequelae. Safety data from the renal transplant population have been reassuring. Azathioprine is generally regarded to be safe when used at dosages of 2 mg/kg or less.¹³

BOX 137.1 PREDICTORS OF A HIGH-RISK PREGNANCY IN WOMEN WITH SYSTEMIC LUPUS ERYTHEMATOSUS

History of pregnancy complications and a poor obstetric outcome
 Presence of high-titer antiphospholipid antibodies (anticardiolipin antibodies, β_2 -glycoprotein, and/or lupus anticoagulant)
 Presence of anti-Ro and anti-La antibodies
 Current or previous lupus nephritis or ongoing severe renal impairment
 Advanced maternal age (>40 years)
 Multiple pregnancies
 Use of cytotoxic medications at the time of conception, including high-dose prednisone
 Active flare at the time of, or 6 months before, conception

Cyclophosphamide is contraindicated in pregnancy, along with methotrexate, mycophenolate, leflunomide, and warfarin, because of their teratogenicity. If possible, these medications should be discontinued at least 3 months before conception. Case series focusing on both inadvertent and intentional exposure to cyclophosphamide have shown very high rates of fetal loss, although there are some cases in which healthy, live births occurred in women receiving cyclophosphamide.^{14,15} Inadvertent exposure to leflunomide, followed by cholestyramine washout, was not associated with adverse fetal outcomes in one small study.¹⁶

MATERNAL AND FETAL COMPLICATIONS DURING PREGNANCY

Although pregnancy outcomes in SLE patients have improved dramatically over the past several decades, SLE does pose a risk of potentially serious maternal and fetal complications. The majority of SLE pregnancies result in normal fetal outcomes, and the annual mortality rate among pregnant SLE patients is comparable to that in those who are not pregnant. The risk of thrombosis, infection, thrombocytopenia, cesarean section, preterm labor, and preeclampsia is significantly increased in SLE patients compared with healthy women.¹⁷

Distinguishing changes of normal pregnancy from lupus flares

Distinguishing between true flares of SLE and normal complications of pregnancy can be difficult. Skin rashes commonly occur in pregnancy; facial

TABLE 137.1
Potential concerns of commonly used pharmaceuticals and biologic agents in pregnancy and lactation

Agent	Safety in pregnancy	Comments	FDA rating	Safety in lactation
Azathioprine	Probably safe	Risk of immunosuppression in fetus, but renal transplant and lupus pregnancy data suggest safety in pregnancy without adverse effects.	D	Probably safe—enters breast milk at low levels but no reports of adverse pediatric events. Caution advised.
Belimumab	Unknown	No human studies but theoretical risk of fetal immunosuppression. Discontinue before pregnancy.	C	Unknown and not recommended.
Corticosteroids	Probably safe	Some reports of prematurity and cleft palate.	C	Probably safe at low dosages under 20 mg/day but does enter breast milk.
Cyclophosphamide	Unsafe	Teratogenic—do not use except in life-threatening manifestations of SLE.	D	Unsafe—enters breast milk
Cyclosporine	Possibly safe	Renal transplant data suggest fetal growth restriction and prematurity in up to 40% of fetuses, but no increased birth defects.	C	Possibly safe—enters breast milk at low levels so fetal monitoring recommended.
Heparin, unfractionated and low molecular weight	Safe	Does not cross the placenta. Low-molecular-weight heparin preferred.	C	Safe—does not enter breast milk.
Hydroxychloroquine	Safe	Numerous benefits in pregnancy and should be continued.	C	Safe—enters breast milk but approved by American Academy of Pediatrics for breastfeeding.
Intravenous immunoglobulin	Probably safe	Crosses the placenta but has been used without any fetal adverse effects.	C	Probably safe but does enter breast milk so use with caution.
Leflunomide	Unsafe	Teratogenic—discontinue at least 3 mo before pregnancy and use washout method with cholestyramine for at least 3 mo if needed.	X	Unknown if it enters breast milk but considered high risk.
Methotrexate	Unsafe	Teratogenic—discontinue at least 3 mo before pregnancy.	X	Probably unsafe.
Mycophenolate	Unsafe	Teratogenic—consider azathioprine as an alternative.	D	Unknown if it enters breast milk so do not use.
NSAIDs	Probably unsafe	Increased risk of miscarriage, oligohydramnios, and prematurity.	C	Probably safe. Ibuprofen preferred.
Rituximab	Unknown	Very limited data, but preterm births and infectious/hematologic abnormalities reported.	C	Unknown and therefore not recommended.
Sulfasalazine	Probably safe	Crosses placenta so small risk of kernicterus in the newborn, but no reported malformations.	B	Probably safe with few reported adverse pediatric effects.
Warfarin	Unsafe	Teratogenic	X	Probably safe—no increased reports of bleeding.

blush, palmar erythema, and mild alopecia should be distinguished from a true lupus-related rash. Arthralgias, myalgias, and backaches are normal symptoms of pregnancy and can usually be managed conservatively with acetaminophen and physical therapy. True synovitis does not occur in normal pregnancy and can be related to a lupus flare. Mild anemia and thrombocytopenia are normal variants of pregnancy, but severe anemia and thrombocytopenia may be an indication of an immune-mediated process, such as immune-mediated thrombocytopenia or hemolytic anemia. The presence of leukopenia and lymphopenia should raise the suspicion of a systemic autoimmune process. A rise in C3 and C4 levels is a normal variation of pregnancy and this can make identifying an SLE flare difficult, so normal complement levels should not automatically be interpreted as an indication of disease quiescence. Double-stranded DNA, however is not affected by pregnancy and can increase when SLE is uncontrolled.

In normal pregnancy, the glomerular filtration rate increases from 100 mL/min to 150 mL/min, with intravascular volume increasing by one third. Patients who have preexisting renal damage and cardiopulmonary compromise may not be able to withstand these changes and may experience preeclampsia or cardiopulmonary failure as a result. It is normal for a mild increase in proteinuria to occur.

Lupus nephritis and preeclampsia

Differentiating between lupus nephritis and preeclampsia can be challenging since both are characterized by proteinuria and hypertension and the two can sometimes be superimposed on each other in the third trimester (Table 137.2). Preeclampsia is defined as new-onset systolic blood pressure of more than 140 mm Hg or diastolic blood pressure of more than 90 mm Hg in the setting of proteinuria (more than 300 mg of protein per 24 hours) after the 20th week of pregnancy. Severe preeclampsia is defined as systolic blood pressure higher than 160 mm Hg or diastolic blood pressure higher than 110 mm Hg with proteinuria of more 5 g protein per day in the presence of pulmonary edema, oliguria, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count), intrauterine growth retardation, or oligohydramnios.

Physiologically, some degree of proteinuria, up to 300 mg of protein over 24 hours, is considered a normal variant of pregnancy. If a woman had some proteinuria before pregnancy, even an increase to 1 g can occur in the absence of lupus nephritis. The serum creatinine concentration, however, tends to decrease.

In a study of unselected lupus patients followed prospectively through pregnancy 64% of those patients who had a history of nephritis (regardless of glomerular filtration rates) experienced preeclampsia, compared with 14% of patient without nephritis.¹⁸ Women with SLE are at increased risk of preeclampsia and thus should be considered for daily aspirin therapy. Aspirin treatment decreases the risk not only of preeclampsia but also of preterm delivery, even in high-risk patients without SLE.¹⁹

Antiphospholipid antibodies

Antiphospholipid antibodies, including moderate- to high-titer anticardiolipin antibodies (immunoglobulin G or immunoglobulin M), β_2 -glycoprotein, and/or lupus anticoagulant, are found in up to one third of SLE patients and present management challenges, particularly in the setting of pregnancy. The presence of antiphospholipid antibodies becomes known as

antiphospholipid syndrome when their presence is accompanied by recurrent pregnancy loss and/or thrombosis. Of the three types of antiphospholipid antibodies, the lupus anticoagulant carries the worse prognosis and is a strong indicator of potential complications.²⁰

Antiphospholipid antibodies are associated with placental insufficiency, reduced amniotic fluid, fetal growth retardation, and sometimes fetal death. Although thrombosis and/or severe or early preeclampsia can occur, it is not uncommon for the mother to be completely asymptomatic while trouble is brewing for the developing fetus.

The pathogenesis behind the morbidity and mortality associated with antiphospholipid antibodies is not fully understood, but harm from antiphospholipid antibodies occurs at the level of the placenta, either from placental thrombosis, direct damage to the placenta, or defective placentation. Antiphospholipid antibodies cause complement activation at the placenta; this in turn activates tissue factor, which leads to a burst of inflammation from neutrophils and oxidative stress.²¹ This results in pregnancy loss through damage to the decidual tissues. Other models suggest that fetal loss is caused by the binding of anti- β_2 -glycoprotein antibodies to trophoblast cells, which inhibits their growth.²²

For women who are asymptomatic carriers of antiphospholipid antibodies with no history of pregnancy loss or thrombosis, treatment is generally not needed. Nevertheless, some rheumatologists prefer to prescribe low-dose aspirin for these patients. In women at higher risk, including those with a history of recurrent pregnancy loss or thrombosis, treatment options include low-dose aspirin combined with either unfractionated heparin 5000 to 12,000 units subcutaneously twice daily or enoxaparin 1 mg/kg subcutaneously daily. Generally, a prophylactic heparin dose is favored in women with a history of pregnancy loss, whereas a full dose is given to women with a history of thrombosis. Combination therapy with heparin and aspirin appears to be superior to treatment with aspirin alone in producing live births.²³ For women in whom combination therapy has been ineffective (occurrence of pregnancy loss or thrombosis despite treatment), intravenous immunoglobulin, corticosteroids, and plasmapheresis are treatment options, although the evidence for their effectiveness is questionable. Treatment of high-risk patients is continued for at least 6 to 8 weeks after delivery because of a continuing thrombosis risk in the postpartum period. Women with a history of recurrent thrombosis may need lifelong treatment. Despite the risks associated with the presence of antiphospholipid antibodies, live births have been reported in over 50% to 74% of such patients when treatment was initiated.²³

Neonatal lupus

Antibodies directed toward anti-Ro and anti-La proteins can cross the placenta and create a syndrome known as *neonatal lupus*. The most common manifestation is a photosensitive rash that appears in the infant around 4 to 6 weeks after birth and occurs in up to 20% of infants born to mothers with the anti-Ro antibody. Although this can occur as the classic malar/butterfly rash, more commonly it consists of nonscarring large, circular macules over the face, trunk, and extremities. The rash usually disappears on its own but can be treated with topical corticosteroids.

Hematologic abnormalities including thrombocytopenia and neutropenia, and hepatic abnormalities such as asymptomatic transaminitis can occur in 10% to 15% of cases. These abnormalities often dissipate as the presence of maternal antibodies in the infant diminishes by months 6 to 8

TABLE 137.2 Distinguishing lupus nephritis from preeclampsia

Factor	Lupus nephritis	Preeclampsia (20 wk of gestation and beyond)
Timing	Throughout pregnancy—occurs over weeks to months	Restricted to third trimester—occurs over hours to days
Hypertension	Sometimes present	Always present
Double-stranded DNA	Increased	Normal
Complement levels (C3, C4)	Low/normal	Normal
Serum uric acid level	Unchanged (unless in the presence of renal insufficiency)	Increases
History of preeclampsia	No impact on subsequent pregnancies	Increased risk in subsequent pregnancies
History of lupus nephritis	Increased risk of flare in pregnancy	Increased risk of preeclampsia
Active urine sediment	Yes—cellular and granular casts	No
Renal biopsy	May be indicated	Not indicated
Delivery	Proteinuria and hypertension do not resolve	Rapid resolution of proteinuria and hypertension

of life. For this reason, routine screening of newborns for these abnormalities is not recommended.

The most serious complication of neonatal lupus, however, is congenital heart block, believed to affect approximately 2% of offspring exposed to anti-Ro antibodies.²⁴ This risk increases up to 20% in subsequent pregnancies following the birth of an infant with anti-Ro antibody-associated congenital heart block and may be amplified by the coexistence of hypothyroidism and anti-La antibodies.²⁵⁻²⁷ Passage of anti-Ro antibodies from mother to fetus is not the exclusive cause of congenital heart block; fetal genetic factors and hypoxia may also play a role.

Although the survival rate for infants with neonatal lupus and congenital heart block is 80% at 1 year, the majority of these infants will need the placement of a permanent pacemaker. Recognizing the risk factors predisposing to this condition is imperative because complete heart block can develop rapidly and is relatively irreversible once it occurs. Since congenital heart block usually develops between 18 and 24 weeks' gestation, some experts recommend serial fetal echocardiography during this period. Premature atrial contractions and even moderate pericardial effusions should be taken seriously, because these may foreshadow the development of congenital heart block. If first- or second-degree heart block is detected, treatment with dexamethasone should be initiated immediately. However, the administration of steroids for prophylactic purposes is not advised, even in women with a history of congenital heart block in the fetus, due to the adverse effects that steroids can have on the fetus (intrauterine growth retardation and preterm birth).²⁸ Maternal hydroxychloroquine therapy has been associated with a reduced risk of cardiac neonatal lupus, and this is another reason it should be continued throughout pregnancy.²⁷ Fortunately, if fetal heart block does not occur in the womb, it is unlikely to manifest itself after delivery.

MANAGEMENT

Monitoring

The rheumatologist should participate actively with an obstetrician skilled in the care of high-risk pregnancies in the management of all pregnant

patients with SLE. The rheumatologist's role is to observe for signs or symptoms of active disease, to help diagnose thrombocytopenia and proteinuria should either occur, to advise on maternal medications, and to advise on risks regarding antiphospholipid syndrome and neonatal lupus. Ordinarily the rheumatologist should see a well patient at least once each trimester and an ill patient more frequently during the pregnancy.

Labor and delivery

In women with a history of antiphospholipid antibodies, important considerations at the time of delivery include the discontinuation of low-molecular-weight heparin at least 48 hours before a planned procedure. Many physicians choose to convert at 35 weeks' gestation to unfractionated heparin, which can be continued up to 6 hours before a procedure, particularly in patients at very high risk of thrombosis. The obstetrician should also be alerted to organ system complications that could impact delivery. For instance, in lupus patients with a history of avascular necrosis of the hips, a spontaneous vaginal delivery may cause musculoskeletal damage, so that a planned cesarean section is warranted.

Although there are no restrictions on breastfeeding, certain medications used in lupus are harmful to the neonate and should be used with caution (see Table 137.1). Others, such as hydroxychloroquine, are considered safe in breastfeeding mothers. The lack of maternal breast milk production may also be an issue for mothers receiving high-dose steroids or in pregnancies that result in preterm birth.

Despite the risks associated with pregnancy and perhaps an increased risk of learning disabilities, children born to women with SLE have normal intelligence and development compared with sex- and gestational age-matched controls.²⁹

Sjögren syndrome

■ ALAN N. BAER ■ JOHN C. HALL

- Sjögren syndrome (SS) is a chronic autoimmune disease characterized by lymphocytic infiltration of the salivary, lacrimal, and other exocrine glands, dryness of the eyes and mouth, and circulating autoantibodies.
- It is best defined as the triad of dry eyes, dry mouth, and evidence of an autoimmune process mediating these and other clinical manifestations.
- It is characterized by a predilection for women of perimenopausal and postmenopausal age, a remarkably stable course in the absence of treatment, diverse symptoms, and heightened risk for B-cell non-Hodgkin lymphoma.
- Antibodies to the small ribonucleoprotein particles SSA and SSB are present in a high proportion of patients.
- SS may occur alone (primary) or together with another well-established systemic autoimmune disease (secondary) such as systemic lupus erythematosus, rheumatoid arthritis, or systemic sclerosis.
- The pathogenesis of SS involves mechanisms leading to targeted inflammation of the lacrimal and salivary glands and B-lymphocyte hyperactivity.
- Management is focused on amelioration of the salivary and lacrimal dysfunction and the use of immunomodulatory or immunosuppressive drugs for certain extraglandular manifestations.

HISTORY

In 1933, Henrik Sjögren, a Swedish ophthalmologist, published a comprehensive description of “keratoconjunctivitis sicca,” including its predilection for menopausal women, frequent occurrence in those with deforming arthritis, and its characteristic impairment of both lacrimal and salivary gland secretion.¹ This eye disease had first been recognized as filamentary keratitis in 1882. Sjögren’s histopathologic description of round cell infiltration and acinar loss in the lacrimal and salivary glands has long been equated with that described by Mikulicz in 1892 in a patient with bilateral lacrimal and salivary gland enlargement.² However, Mikulicz syndrome is now known to arise from a variety of distinct pathologic processes, including lymphoma, leukemia, tuberculosis, IgG4-related disease, and sarcoidosis.

The entity Sjögren syndrome (SS) was defined in 1965 as the triad of dry eyes, dry mouth, and rheumatoid arthritis (RA) or other connective tissue disease.³ Classification criteria for SS have evolved with better understanding of the disease and the development of new tests, including anti-SSA and anti-SSB antibodies, minor salivary gland biopsy, salivary scintigraphy, and new ocular surface-staining methodologies and scoring schema. Over the past decade, SS has been defined with greater rigor, thereby ensuring that the patient’s ocular and oral dryness are mediated by immune mechanisms, which are potentially amenable to modulation with newer systemic therapeutic agents.

EPIDEMIOLOGY

SS is a worldwide disease without notable regional differences. The major demographic and phenotypic features are shown in Table 138.1.⁴⁻⁹ The

disease has a female-to-male ratio of 10:1 or higher and is usually diagnosed between the ages of 40 and 60, but it also affects children and the elderly. The annual incidence of SS ranges from 3.9 to 6.0 per 100,000 inhabitants.¹⁰ Current estimates of prevalence range from 0.05% to 0.7%.

GLANDULAR PATHOLOGY

Lymphocytic infiltration of the salivary and lacrimal glands is associated with loss of acini and ducts (Fig. 138.1). The histopathology in the minor labial salivary glands is termed “focal lymphocytic sialadenitis.” The infiltrates surround the intralobular ducts or blood vessels and consist primarily of CD4+ T and B cells. The lymphoid infiltrate is characteristically focal but can become confluent with more severe disease. The lymphocytic predominance is T cells in small infiltrates and B cells in larger ones.¹¹ The proportion of interstitial IgG- and IgM-secreting plasma cells is increased relative to those that are normally present and secrete IgA.¹² Lymphoid follicles with germinal center (GC)-like structures are present in 25% of labial glands in patients with SS.¹³

Lymphoepithelial lesions are a characteristic histologic feature of the major salivary gland involvement in SS (known as “benign lymphoepithelial sialadenitis”), but such lesions are also found infrequently in the lacrimal and minor salivary glands. They are islands of coalescent ductal epithelial cells infiltrated by marginal zone or monocytoid B cells and surrounded by a dense lymphocytic infiltrate.¹⁴ Benign lymphoepithelial sialadenitis is a known precursor of mucosa-associated lymphoid tissue (MALT) extranodal marginal zone lymphoma and is distinguished by lymphoepithelial lesions surrounded by halos of malignant marginal zone B cells (Fig. 138.2). Differentiation of the benign lesion from MALT lymphoma may be difficult because both may contain monoclonal populations of B cells, reactive GCs, and an admixture of lymphocytes and plasma cells.

CLINICAL FEATURES

Glandular involvement

Ocular manifestations

The dry eye symptoms include burning, scratchiness, foreign body sensation, stinging, soreness, photophobia, and lack of tears. The resultant changes in the refractive properties of the cornea may blur vision. The symptoms are often exacerbated by air drafts, low humidity, reading, and viewing a computer monitor and correlate poorly with objective signs of dry eye disease.

Progressive periductal lymphocytic infiltration develops in the orbital and accessory lacrimal glands. In the conjunctiva, squamous metaplasia, loss of goblet cells, and chronic stromal inflammation occur. The cornea is thin, with focal loss of epithelium leading to exposure of the Bowman membrane. Strands of devitalized cells (filamentary keratitis) may form. Alterations in tear volume and composition, including hyperosmolality, have been postulated to contribute to the ocular surface damage.

Many SS patients may have additional causes of dry eye symptoms (Box 138.1), the most common being meibomian gland dysfunction. Ocular complications include bacterial conjunctivitis and corneal abrasion and ulceration.

Oral manifestations

Symptoms of a dry mouth, termed “xerostomia,” are a key feature but have multiple alternative causes (Box 138.2). A true deficiency of saliva, termed

“salivary hypofunction,” does not always accompany xerostomia but is an expected finding. Patients report difficulty chewing and swallowing dry food, speaking at length, and wearing dentures. They may note impaired taste, thickened saliva, intolerance of acidic and spicy foods, a burning sensation in the mouth and tongue, and dry lips. Dental decay and oral infection often ensue.

On examination the tongue blade characteristically sticks to the buccal mucosa. Infralingual salivary pooling is not seen as the patient elevates the tongue. Caries may be evident at atypical sites, particularly at the junction of the dental crown and root, along the gingival margin, and on the cusp tips and incisal edges of teeth. The dorsal surface of the tongue may be hyperlobulated (Fig. 138.3). Oral candidiasis often accompanies more severe dryness and is manifested as lingual papillary atrophy, patchy or diffuse erythema of the mucosa and dorsal surface of the tongue, and angular cheilitis. The lingual erythema and papillary atrophy can improve with antifungal therapy.

Symmetric, nontender swelling of the major salivary glands occurs in approximately 30% of patients with SS, is generally asymptomatic, and has a broad differential diagnosis (Fig. 138.4, Box 138.3). Acutely painful parotid gland swelling usually represents a supervening bacterial parotitis. Slowly progressive enlargement of the glands should raise concern for the presence of glandular lymphoma, particularly when asymmetric.

Extraglandular manifestations

Primary versus secondary disease

The extraglandular manifestations of SS (Box 138.4) may be inherent or reflect the presence of overlapping systemic lupus erythematosus (SLE), RA, systemic sclerosis, or inflammatory myopathy. SS is termed “secondary” when it occurs with another systemic rheumatic disease (for which the classification criteria are met) and “primary” when such a second disease is absent. In the ensuing discussion of extraglandular manifestations, the focus is on primary SS.

Constitutional symptoms

Persistent fatigue, widespread joint and muscle pain, and cognitive symptoms are reported commonly and often do not correlate with antibody markers of the disease. The fatigue is probably multifactorial and may be associated with depression. Cognitive symptoms include subjective memory loss and difficulty concentrating and are often termed “brain fog” by patients.

Cutaneous involvement

Xerosis and associated pruritus are common. Small-vessel vasculopathies are manifested by palpable and nonpalpable purpura and urticarial lesions (Fig. 138.5) and those of larger blood vessels by livedo reticularis and leg

Fig. 138.1 Focal lymphocytic sialadenitis of Sjögren syndrome. This minor salivary gland shows multiple periductal lymphocytic infiltrates. A germinal center-like structure is evident in one such infiltrate (arrow).

Fig. 138.2 Lymphoepithelial lesion. A myoepithelial island is infiltrated by and surrounded by monocytoïd lymphocytes in this parotid gland specimen from a patient with Sjögren syndrome and mucosa-associated lymphoid tissue lymphoma.

ulcers. Skin lesions of subacute cutaneous lupus erythematosus (SCLE) may develop and on this basis be defined as an SS-SLE overlap syndrome (Fig. 138.6). “Annular erythema of SS” occurs primarily in Asian patients and is characterized by erythematous skin lesions with indurated borders, most often on the upper part of the body. It shares with SCLE a similar morphology and close relationship with anti-SSA and anti-SSB antibodies but lacks a prominent interface dermatitis and HLA-DR3 linkage. Other SS-associated skin lesions include panniculitis, primary nodular cutaneous amyloidosis, and cutaneous B-cell lymphoma.

Musculoskeletal involvement

An intermittent nonerosive symmetric inflammatory polyarthritis occurs in up to 30% of SS patients¹⁵ and particularly affects the fingers, wrists, and ankles. Many SS patients report arthralgia but lack synovitis. More severe forms of arthritis may occur when SS overlaps with another connective tissue disease. Muscle involvement can include a low-grade myositis inclusion body disease or fibromyalgia.

Pulmonary involvement

Pulmonary disease affects 9% to 12% of patients, although pulmonary function tests (PFTs), bronchoalveolar lavage, and computed tomography (CT)

Fig. 138.3 Hyperlobulation of the tongue. Hyperlobulation and fissuring of the tongue are characteristic changes associated with salivary hypofunction in patients with Sjögren syndrome. The papillary atrophy can be a manifestation of oral candidiasis and may be reversed with antifungal therapy.

BOX 138.1 DIFFERENTIAL DIAGNOSIS OF DRY EYE

Primarily evaporative

Lid and ocular surface disease
Meibomian gland dysfunction
Poor lid congruity
Facial nerve paralysis
Low blink rate (e.g., Parkinson disease, video terminal use)
Extrinsic causes that enhance evaporation
Trachoma (vitamin A deficiency)
Use of topical anesthetic drops
Excessive use of preservative-containing drops
Contact lens wear
Allergic conjunctivitis

Primarily aqueous deficient

Sjögren syndrome
Other forms of lacrimal gland disease
Aging
Inflammatory diseases (e.g., acquired immunodeficiency syndrome, sarcoidosis, lymphoma, graft-versus-host disease)
Lacrimal gland duct obstruction from various forms of cicatrizing conjunctivitis
Ocular sensory loss leading to reflex hyposecretion and a diminished blink rate
Corneal surgery
Diabetes mellitus
Neurotrophic keratitis
Chronic contact lens wear
Loss of lacrimal secretory motor function
Drugs (e.g., antihistamines, β -blockers, antispasmodics, diuretics)
Central seventh nerve damage

Adapted from The definition and classification of dry eye disease: report of the Definition and Classification Subcommittee of the International Dry Eye Workshop (2007). *Ocul Surf* 2007;5:75-92.

BOX 138.2 DIFFERENTIAL DIAGNOSIS OF XEROSTOMIA

Drug side effect (e.g., single or multiple prescription of drugs with anticholinergic, diuretic, antihypertensive, anxiolytic, or antihistamine effects)
Salivary gland diseases, including Sjögren syndrome
Poorly controlled diabetes mellitus
Dehydration
Mouth breathing, nasal obstruction
Head and neck irradiation (including high doses of radioactive iodine for thyroid cancer)
Psychological factors

Fig. 138.4 Bilateral parotid gland swelling. Marked swelling of both parotid glands is evident in this young woman with Sjögren syndrome.

BOX 138.3 CAUSES OF BILATERAL SALIVARY GLAND ENLARGEMENT

Infectious

Viral infections (mumps, Epstein-Barr, hepatitis C, human immunodeficiency)

Bacterial

Acute suppurative parotitis

Tuberculosis

Fungal

Autoimmune

Sjögren syndrome

Granulomatous polyangiitis

Inflammatory

IgG4-related disease (including Kuttner tumor)

Allergic parotitis (sialodochitis fibrinosa)

Chronic recurrent parotitis

Kimura disease

Metabolic (causing sialadenosis, which is characterized by painless, bilaterally symmetric parotid enlargement that is soft and nontender on palpation)

Uncontrolled diabetes mellitus

Bulimia

Alcoholism with liver disease

Hyperlipoproteinemia

Neoplastic

Lymphoma

Leukemia

Warthin tumor (papillary cystadenoma lymphomatosum)

Diffuse hyperplastic oncocytic hyperplasia

Granulomatous

Sarcoidosis

Iatrogenic or self-induced

Radioactive iodine

Pneumoparotitis (wind instrument players, glass blowers)

may detect lung abnormalities in up to 75%.¹⁶ SS affects both the upper and lower airways. Salivary deficiency can impair the buffering of refluxed gastric acid and lead to globus, excessive throat clearing, coughing, and hoarseness. Lower airway disease is manifested by dry cough, recurrent bronchitis, and dyspnea. PFTs show mild, small-airway obstruction. Abnormalities on CT include bronchial airway thickening, bronchiectasis, reticular or nodular infiltrates, and air trapping. Transbronchial biopsy specimens demonstrate a subepithelial lymphocytic infiltrate. Chronic inflammation and destruction of submucosal bronchial glands were reported by Sjögren, but the extent to which this occurs in patients with SS is debated. Follicular bronchiolitis is a distinctive pathologic lesion in SS characterized by the formation of hyperplastic lymphoid follicles in the bronchiolar walls and subsequent obstruction of the lumen. A valve phenomenon may result in lung cysts or bullae (Fig. 138.7).

Fig. 138.5 Lesions of palpable purpura are evident on the lower extremity of a patient with Sjögren syndrome.

Hematologic

Leukopenia

Anemia

Thrombocytopenia

Hypergammaglobulinemia

Cryoglobulinemia

Monoclonal gammopathy

Nonspecific, usual, and lymphocytic forms of interstitial pneumonitis (NSIP, UIP, and LIP, respectively) and cryptogenic organizing pneumonia (COP) may be seen and are usually manifested as dyspnea and cough. NSIP is the most common, whereas UIP and COP occur rarely. LIP is the most characteristic of SS and is marked by lymphoplasmacytic infiltration of the

interstitium, lymphocytes in the alveolar spaces, and lymphoid aggregates along lymphatic routes and around blood vessels. Follicular bronchiolitis often coexists. Affected patients usually have a polyclonal or monoclonal gammopathy. LIP can be a precursor to a bronchus-associated lymphoid tissue (BALT) lymphoma. These rare neoplasms are typically associated with a dry cough, absence of lymphadenopathy, and multiple, often bilateral patchy infiltrates or nodules in a peribronchial distribution.¹⁷

Gastrointestinal and hepatic involvement

An increased prevalence of celiac disease has been observed in some studies.¹⁸ Liver disease occurs in up to 20% of patients with SS, the usual forms being primary biliary cirrhosis and autoimmune hepatitis.

Renal involvement

Clinical renal disease develops in 5% of patients, although a much larger number may have latent involvement. Tubulointerstitial nephritis is most common, tends to occur in younger patients with a shorter duration of disease, and may be manifested as polyuria secondary to hyposthenuria (nephrogenic diabetes insipidus), renal colic, or tubular proteinuria (or any combination of the three). The clinical course is most often indolent, with mild to moderate renal dysfunction.^{19,20} Distal (type I) renal tubular acidosis (RTA) is usually evident and is characterized by an inability of the distal nephron to acidify the urine. Urine pH is higher than 5.5 despite the presence of metabolic acidosis. Patients may have renal potassium wasting and hypercalciuria with potential for the development of hypokalemic paralysis, renal stones, and nephrocalcinosis. Affected patients usually have hypergammaglobulinemia. RTA may be evident only with an ammonium chloride-loading test. Proximal RTA occurs rarely and has features of Fanconi syndrome, including glucosuria, aminoaciduria, phosphaturia, and

uricosuria. Membranoproliferative and mesangioproliferative glomerulonephritides occur rarely as late disease manifestations; are characterized by renal dysfunction, hematuria, or proteinuria (or any combination); and are generally associated with cryoglobulinemia.²⁰

Gynecologic involvement

Vaginal symptoms, including dryness, pruritus, and dyspareunia, are frequent, partly because of the predilection of postmenopausal women for SS. Gynecologic examination does not show an increased prevalence of atrophic changes relative to age-matched controls.²¹ The vagina has no secretory glands. The genital dryness has been postulated to arise from involvement of the Bartholin and minor vestibular glands, but this has not been confirmed.

Neurologic involvement

Both central nervous system (CNS) and peripheral nervous system involvement may occur. Peripheral neuropathy is evident in approximately 20% of SS patients²² and has several forms, the most common being a pure sensory neuropathy.^{23,24} Patients may have more than one type of neuropathy. The symptoms often precede the diagnosis of SS and can occur without overt sicca.^{23,24} Certain forms of peripheral neuropathy can arise as a primary manifestation of the disease, independent of other extraglandular manifestations, whereas others are complications of a systemic vasculopathy.

Pure sensory neuropathy is characterized by loss of small axons with prominent neuropathic pain, loss of pinprick or temperature discrimination, and hyperesthesia. The results of nerve conduction studies are generally normal. The diagnosis is supported by a reduction in the number or abnormal morphology of the intraepidermal nerve fibers on punch skin biopsy specimens. Many affected patients have an asymmetric and non-length-dependent distribution of pain, with involvement of the face, trunk, and limbs. They are often older and have a lower frequency of anti-SSA and anti-SSB antibodies, rheumatoid factor (RF), and hypergammaglobulinemia than do nonaffected patients.^{22,24}

Sensory neuronopathy arises from primary damage to the dorsal root ganglia sensory neurons with subsequent degeneration of short- and long-length axons. Ataxia, loss of deep tendon reflexes, and proximal and distal sensory symptoms, frequently in an asymmetric pattern, are typical. Joint position sense is impaired, with a positive Romberg sign and pseudoathetosis, but muscle strength is preserved. An Adie pupil is often observed. Magnetic resonance imaging (MRI) may show high-intensity T2 signal in the posterior columns of the spinal cord. Biopsy specimens of dorsal root ganglia have shown T-lymphocytic infiltrates around individual neurons.²⁴ Sensory ataxia develops in some patients with painful small-fiber sensory neuropathy, and it has been speculated that these two peripheral neuropathies may share a common pathogenesis.

Sensorimotor neuropathies occur at the same frequency as pure sensory neuropathies and involve large-diameter fibers.²² The usual form is an axonal neuropathy with symmetric sensory deficits in a stocking-glove distribution, impaired vibration sense, mild distal muscle weakness, and diminished or absent tendon reflexes. This form of axonal sensorimotor polyneuropathy is usually associated with systemic disease, including vasculitis, monoclonal proteins, and lymphoma. Demyelinating sensorimotor, cranial, autonomic, and mononeuritis multiplex are rare forms of neuropathy in SS.

Fig. 138.6 Subacute cutaneous lupus overlap rash. This patient with Sjögren syndrome and anti-SSA antibodies has annular polycyclic lesions consistent with subacute cutaneous lupus.

Fig. 138.7 (a and b) Cystic lung lesions. These computed tomography images show multiple thin-walled pulmonary cysts in a woman with Sjögren syndrome.

CNS disease in SS is most commonly a subacute encephalopathy characterized by memory loss, cognitive dysfunction, visual disturbances, dizziness, and impaired concentration and attention.²⁵ MRI may show small punctate white matter T2 hyperintensities in the subcortical and periventricular areas. These white matter lesions occur commonly as a function of age and cerebrovascular risk factors, and their presence in SS patients may thus be difficult to interpret.²⁵ Demyelinating disease resembling multiple sclerosis in SS patients was first reported in 1986,²⁶ but there is doubt about the generalizability of these initial observations. SS has been associated with the neuromyelitis optica spectrum of CNS demyelinating disorders, which is defined by the presence of longitudinally extensive transverse myelitis, optic neuritis, and aquaporin-4 antibodies.

Endocrine involvement

Autoimmune thyroid disease is present in approximately 15% to 30% of patients with SS.^{27,28}

Systemic vasculitis

Vasculitis affects 10% of SS patients and most often involves small blood vessels of the skin, peripheral nerves, and kidneys. Biopsy specimens of purpuric or urticarial skin lesions most often show leukocytoclastic vasculitis. Rare ulcers on the lower part of the legs should prompt a search for serum cryoglobulins. Cutaneous vasculitis is associated with anti-SSA antibodies, RF, cryoglobulins, hypergammaglobulinemia, and frequently signs of systemic involvement, including peripheral neuropathy and glomerulonephritis.

Hematologic abnormalities

Anemia, leukopenia (usually neutropenia), and thrombocytopenia each occur in up to 20% of patients, often in association with each other and serologic disease markers.^{29,30} Hypergammaglobulinemia is found in 20% to 40%, correlates with the presence of anti-SSA and anti-SSB antibodies and RF,^{9,30} and can be pronounced, with globulin levels reaching 4 to 6 g/dL. Monoclonal immunoglobulins, often in small amounts, are present in up to 20% of SS patients.^{9,30} Cryoglobulinemia occurs in 10% to 15% of patients with SS, frequently in association with leukocytoclastic vasculitis and hypocomplementemia. The cryoglobulin is most often mixed, with monoclonal IgMκ RF and polyclonal IgG components being present. Affected patients are at higher risk for B-cell lymphoma and life-threatening vasculitis and should be tested for hepatitis C.³¹

SYSTEMIC AUTOIMMUNITY

Antinuclear antibodies (ANAs) are found in up to 90% of patients,³² the most common being directed against the SSA(Ro)/SSB(La) ribonucleoprotein complex in 60% to 80% of patients. These antibodies to SSA and SSB are not always detectable with a fluorescent ANA test. Antibodies to SSA alone are found with approximately equal frequency as antibodies to both SSA and SSB, whereas antibodies to SSB alone are uncommon in patients with SS.³³ The anti-SSA and anti-SSB antibody profile present at diagnosis generally remains unchanged during the subsequent disease course,³⁴ with the exception of low-titer test results. Anti-SSA and anti-SSB antibodies are associated with a higher prevalence of extraglandular features and more extensive lymphoid infiltrates in the salivary glands.³⁵ RF is found in 40% to 50% of SS patients, usually those with anti-SSA antibodies.

Anticentromere antibodies define a subset of 5% of SS patients with more frequent Raynaud phenomenon and associated autoimmune diseases, especially limited systemic sclerosis and primary biliary cirrhosis.³⁶ Anti-cyclic citrullinated peptide antibodies, present in 5% to 10% of patients, are associated with nonerosive synovitis.³⁷ Antibodies to the cytoskeletal protein α -fodrin are found in 30% to 90% of SS patients, are relatively specific for the diagnosis, but do not have better sensitivity and specificity than anti-SSA and anti-SSB antibodies do.³⁸ Antimitochondrial antibodies are a reliable marker of autoimmune cholangitis in 5% of SS patients,³⁹ but the more prevalent anti-smooth muscle antibodies are a marker of autoimmune hepatitis only when present in high titer.⁴⁰

Antibodies to the muscarinic acetylcholine receptor (M3R) have been postulated to mediate the decrease in salivary and lacrimal gland secretion in SS, but progress has been slow in confirming this.^{32,41}

ASSOCIATION WITH OTHER AUTOIMMUNE DISEASES

Patients with SS have an increased prevalence of other autoimmune diseases, including celiac disease, thyroiditis, primary biliary cirrhosis, and various systemic rheumatic diseases.¹⁸ SS can be diagnosed in 9% to 14% of patients

with SLE^{42,43} and in 7% to 25% of those with RA.^{44,45} The concept of secondary SS has long implied the presence of serologic, pathologic, and genetic features distinct from those of primary SS, but this is now being challenged. SS patients are often found to have clinical features and serologic markers of more than one rheumatic disease at the time of diagnosis. Thus it is often not possible to classify one disease as secondary to another.⁴⁶ Some differences in the phenotypic expression of SS occurring in the context of other rheumatic diseases have been demonstrated.⁴³

LYMPHOPROLIFERATIVE DISEASE

Patients with SS have a 16- to 19-fold increased risk for the development of non-Hodgkin B-cell lymphoma.^{8,47} The risk is generally higher for primary than for secondary SS and exceeds that of any other autoimmune disease.⁴⁸ The cumulative incidence of non-Hodgkin lymphoma in SS cohorts is 5% to 10% and increases with duration of follow-up. Markers of severe disease are associated with increased risk and include persistent parotid gland enlargement, palpable purpura, cryoglobulinemia, monoclonal proteins, hypocomplementemia, CD4+ lymphocytopenia, and the presence of GC-like structures in baseline labial gland biopsy specimens.⁴⁹

Most SS-associated lymphomas are the marginal zone B-cell subtype, particularly those of MALT origin, and arise in the salivary glands but also occasionally in the stomach, orbital adnexa, nasopharynx, lungs, kidneys, liver, and skin. They are usually low grade and characterized by a small tumor burden.⁵⁰ MALT lymphomas are present at more than one extranodal site in 20% of patients and may disseminate to other sites, including other salivary glands, the lacrimal glands, lung, stomach, and cervical nodes. Infiltration into bone marrow is rare. Diffuse large B-cell lymphoma occurs in SS patients at a frequency roughly equivalent to that of MALT lymphoma^{8,50} and may arise *de novo* or in the setting of a preexisting low-grade MALT lymphoma. It is characterized by older age and advanced anatomic stage at initial evaluation and a median overall survival of less than 2 years.⁵¹

The development of lymphoma is often heralded by persistent enlargement of the salivary or lacrimal glands or a new mass within one of the glands. Affected patients frequently have extraglandular disease.^{8,51} Evaluation of a salivary mass or persistent salivary or lacrimal gland enlargement begins with an initial fine-needle aspiration or core needle biopsy under ultrasound guidance and immunophenotyping by flow cytometry to differentiate benign from potentially malignant lesions. However, the finding of a monoclonal B-cell population does not necessarily indicate the presence of malignant lymphoma. Diagnosis of MALT lymphoma may require additional tissue secured by incisional biopsy or superficial parotidectomy.

NATURAL HISTORY

SS progresses very slowly in the majority of patients in the absence of treatment, without rapid deterioration in salivary or tear gland function or dramatic changes in symptoms or markers of systemic disease activity.^{52,53} Serologic parameters also remain relatively stable, with the exception of an oft-observed decline in IgG levels.^{53,54} Lymphocytic infiltration of the labial salivary glands increases in the majority of patients after intervals of 1 to 12 years, but few studies have been performed.⁵⁵ Mortality in patients with SS is not significantly different from that in the general population.⁵⁴

CLASSIFICATION CRITERIA

The 2012 American College of Rheumatology (ACR) provisional classification criteria for SS were developed primarily for clinical trials, where protocol-driven assessment of ocular surface staining and interpretation of labial gland biopsy findings can be applied rigorously (Box 138.5).^{46,56,57} The most widely accepted classification criteria are those proposed in 2002 by the American-European Consensus Group (AECG) (Box 138.6).⁵⁸ These criteria have not been endorsed by the ACR or European League Against Rheumatism (EULAR) but are widely used in clinical practice, in part because certain component tests, such as the Schirmer test and the whole unstimulated saliva collection, can be performed easily. They have been criticized for their inclusion of patient symptoms, which correlate poorly with objective measures of salivary and lacrimal gland function, yet may constitute 50% of the requisite criteria for diagnosis in an individual patient. The component diagnostic tests for ocular and oral dryness are not diagnostically equivalent. The ACR classification criteria will soon undergo external validation and comparison with the AECG criteria for the purpose of developing a definitive set endorsed by both the ACR and EULAR.

BOX 138.5 AMERICAN COLLEGE OF RHEUMATOLOGY PROVISIONAL CLASSIFICATION CRITERIA FOR SJÖGREN SYNDROME

The classification of SS, which applies to individuals with signs or symptoms that may be suggestive of SS, will be met in patients who have at least two of the following three objective features:

1. Positive serum anti-SSA/Ro and/or anti-SSB/La or positive rheumatoid factor and ANA titer $\geq 1:320$
2. Labial salivary gland biopsy specimen exhibiting focal lymphocytic sialadenitis with a focus score of 1 or more foci per 4 mm²*
3. Keratoconjunctivitis sicca with an ocular staining score of 3 or higher (assuming that the individual is not currently using eye drops daily for glaucoma and has not undergone corneal surgery or cosmetic eyelid surgery in the last 5 years)[†]

A previous diagnosis of any of the following conditions would exclude participation in SS studies or therapeutic trials because of overlapping clinical features or interference with criteria tests:

History of head and neck radiation treatment
Hepatitis C infection
Acquired immunodeficiency syndrome
Sarcoidosis
Amyloidosis
Graft-versus-host disease
IgG4-related disease

*Using histopathologic definitions and focus score assessment methods as previously described.⁵⁶

[†]Using the ocular staining score as previously described.⁵⁷

ANA, antinuclear antibody; SS, Sjögren syndrome.

From Shiboski SC, Shiboski CH, Criswell L, et al. American College of Rheumatology classification criteria for Sjögren's syndrome: a data-driven, expert consensus approach in the Sjögren's International Collaborative Clinical Alliance Cohort. *Arthritis Care Res (Hoboken)* 2012;64:475-87.

DIAGNOSTIC EVALUATION

The diagnosis of SS is most often established with an objective measure of ocular dryness or salivary hypofunction coupled with evidence of underlying autoimmunity.

Ophthalmologic examination

The ophthalmologic examination should include an assessment of tear production (Schirmer test) and ocular surface staining. The latter offers the greatest utility for the diagnosis of dry eye disease and is performed with lissamine green (for the conjunctiva) and fluorescein (for the cornea) (Fig. 138.8). These dyes stain corneal epithelium stroma (thereby revealing defects in the corneal epithelium) and devitalized conjunctival cells. Thresholds of staining that correlate best with other SS phenotypic features have been established.^{57,59} The Schirmer test measures the 5-minute wetting of a standardized strip of filter paper placed in the lower lateral fornix of the eyelid and serves as an indicator of basal (anesthetized) or stimulated (unanesthetized) tear flow. The unanesthetized Schirmer test is supportive of SS when wetting measures 5 mm or less in either eye. This is a stringent cutoff value and thus decreases the sensitivity of the test in patients with mild SS. Schirmer test results decline with age, and therefore the test may not be appropriate for elderly individuals.⁵⁹

Major salivary glands

Salivary flow measurements document gland hypofunction and are measured either with or without stimulation. The whole unstimulated saliva flow rate correlates best with xerostomia and is most relevant to oral health and dental integrity because it reflects the basal flow present throughout the majority of the day, which stems primarily from the submandibular and sublingual glands. Whole unstimulated sialometry requires an analytic balance to weigh the specimen container before and after saliva collection. The patient should not have eaten, chewed gum, or drank water for the preceding 90 minutes. The patient then empties the saliva every minute into a preweighed cup for a period of 5 to 15 minutes.⁶⁰ The volume of saliva is determined by weight, with the specific gravity assumed to be 1 g/mL and less than 0.1 mL/min being considered abnormal. Saliva secretion after an olfactory, gustatory, or masticatory stimulus is larger in volume, involves the parotid glands, and facilitates eating. "Whole" stimulated saliva production can be measured by expectoration or suction of saliva produced after the

BOX 138.6 AMERICAN-EUROPEAN CONSENSUS GROUP CLASSIFICATION CRITERIA FOR SJÖGREN SYNDROME

1. Ocular symptoms: a positive response to at least one of the following questions:
 - Have you had daily, persistent, troublesome dry eyes for more than 3 months?
 - Do you have a recurrent sensation of sand or gravel in your eyes?
 - Do you use tear substitutes more than three times a day?
2. Oral symptoms: a positive response to at least one of the following questions:
 - Have you had dry mouth for more than 3 months?
 - Have you had recurrently or persistently swollen salivary glands as an adult?
 - Do you frequently drink liquids to aid in swallowing dry food?
3. Ocular signs: objective evidence of ocular involvement defined as a positive result on at least one of the following two tests:
 - Schirmer test performed without anesthesia (5 mm in 5 minutes)
 - Rose Bengal score or other ocular dry score (4 or higher according to the van Bijsterveld scoring system)
4. Histopathology: focal lymphocytic sialadenitis as evaluated by an expert histopathologist in minor salivary glands (obtained through normal-appearing mucosa) with a focus score of 1 or higher; the focus score is defined as the number of lymphocytic foci (which are adjacent to normal-appearing mucous acini and contain more than 50 lymphocytes) per 4 mm² of glandular tissue
5. Salivary gland involvement: objective evidence of salivary gland involvement defined by a positive result on at least one of the following diagnostic tests:
 - Unstimulated whole salivary flow (≥ 1.5 mL in 15 minutes)
 - Parotid sialography showing the presence of diffuse sialectases (punctate, cavitary, or destructive pattern) without evidence of obstruction of the major ducts
 - Salivary scintigraphy showing delayed uptake, reduced concentration, or delayed excretion of tracer
6. Autoantibodies: presence in the serum of one or both of the following autoantibodies:
 - Antibodies to Ro (Sjögren syndrome A) antigens
 - Antibodies to La (Sjögren syndrome B) antigens

Revised rules for classification

For primary Sjögren syndrome

In patients without any potentially associated disease, primary Sjögren syndrome may be defined as follows:

- The presence of any four of the six items indicative of primary Sjögren syndrome as long as either histopathology or serology is positive
- The presence of any three of the four objective criteria items (i.e., items 3, 4, 5, and 6)

For secondary Sjögren syndrome

In patients with a potentially associated disease (e.g., another well-defined connective tissue disease), the presence of item 1 or item 2 plus any two from among items 3, 4, and 5 may be considered as being indicative of secondary Sjögren syndrome.

Exclusion criteria

- Past head and neck radiation treatment
- Hepatitis C infection
- Acquired immunodeficiency syndrome
- Preexisting lymphoma
- Sarcoidosis
- Graft-versus-host disease
- Use of anticholinergic drugs (since a time shorter than fourfold the half-life of the drug)

From Vitali C, Bombardieri S, Jonsson R, et al. Classification criteria for Sjögren's syndrome: a revised version of the European criteria proposed by the American-European consensus group. *Ann Rheum Dis* 2002;61:554-8.

patient chews on paraffin or gum for a period of 5 to 15 minutes or has taken pilocarpine 60 minutes earlier.⁶⁰ Levels lower than 0.7 mL/min define salivary hypofunction.⁶¹

Salivary gland structure is assessed with various imaging modalities (Fig. 138.9). Contrast-enhanced sialography reveals abnormalities indicative of damage to the ductal structures or parenchyma of the parotid gland. Dilatation of the terminal ducts (sialectasia) and loss of intraglandular ductal branching are the most typical findings. This test is difficult to perform, may be painful, and can lead to infection, thus prompting a preference for other modalities. MRI reliably demonstrates the glandular changes associated with SS, including an inhomogeneous pattern of the parenchyma on both T1- and

Fig. 138.8 Advanced keratoconjunctivitis sicca in a patient with Sjögren syndrome visualized with fluorescein (a) and lissamine green (b) staining of the ocular surface. Multiple defects in the epithelium of the interpalpebral cornea are evident as fluorescein-staining dots (a). A triangular area of staining of the interpalpebral temporal conjunctiva is evident with lissamine green (b). (From Whitcher JP, Shiboski CH, Shiboski SC, et al. A simplified quantitative method for assessing keratoconjunctivitis sicca from the Sjögren's Syndrome International Registry. *Am J Ophthalmol* 2010;149:405-15. With permission from Elsevier.)

Fig. 138.9 Imaging of the parotid glands in Sjögren syndrome. (a) Contrast-enhanced sialogram in a patient with Sjögren syndrome. The multiple small round opacities present at the termination of the smaller ducts (sialectasia) has led to the appearance of a branchless fruit-laden tree or "mulberry" pattern. (b) Magnetic resonance imaging. On this T1-weighted image, both hypointense cystic structures and hyperintense foci are evident in the parotid gland parenchyma. (c) Computed tomography. In this tomographic section, punctate areas of calcification are apparent in the parotid gland parenchyma. This image is from a study of the same patient as in panel b. (d) Ultrasonography. Note the parenchymal inhomogeneity with numerous rounded hypoechoic areas delineated by hyperechoic linear reflectors.

T2-weighted sequences and multiple hypointense and hyperintense foci of varying size leading to a mottled or salt-and-pepper appearance. Dilation of the ductal system appears hypointense on T1-weighted and hyperintense on T2-weighted images. CT may demonstrate punctate calcification throughout the parotid gland parenchyma; it is used mainly for evaluation of sialolithiasis. Ultrasonography is emerging in importance because it can be performed in the clinical setting and does not involve radiation. It reveals variable degrees of parenchymal inhomogeneity amenable to scoring.

Salivary gland scintigraphy provides a functional analysis of the major salivary glands through measurement of the uptake, concentration, and excretion of technetium pertechnetate with a gamma scintillation camera. It has good sensitivity but fairly low specificity for SS and lacks standardized criteria for abnormal test results, which has led to variation in interpretation between centers.

Labial gland biopsy

Labial salivary gland biopsy is essential for definitive evaluation of patients with suspected SS who lack both anti-SSA or anti-SSB antibodies or have weakly positive test results. Additionally, it may provide useful prognostic information on all SS patients⁴⁹ and establish alternative diagnoses,

including amyloidosis, sarcoidosis, IgG4-related disease, and lymphoma. However, it may cause persistent lip numbness in up to 2% of patients.⁶² The preferred biopsy technique is that described by Daniels and colleagues (<http://sicca.ucsf.edu/Oral-Saliva-SOP.pdf>). Approximately six to seven minor salivary glands should be dissected free, fixed in formalin, and embedded whole in paraffin as a group. Interpretation of the biopsy specimen must be performed according to the protocols used for deriving the 2012 ACR classification criteria.⁵⁶

Focal lymphocytic sialadenitis is characteristic of SS and defined by the presence of tightly aggregated clusters or foci of lymphocytes containing 50 or more cells (see Fig. 138.1). Because such lymphocytic foci can also occur in glands that have sustained damage from ductal obstruction, they should be considered a feature of focal lymphocytic sialadenitis only if they are adjacent to normal-appearing mucous acini. The number of lymphocytic foci normalized to 4 mm² of glandular section area is termed the "focus score" and provides a semiquantitative assessment of histologic severity. It is measured in a midspecimen tissue section by counting the number of foci, measuring the total glandular area in the section with a calibrated eyepiece graticule, and then calculating the number of foci per 4 mm² (Fig. 138.10). A score of 1 focus per 4 mm² or higher correlates strongly with the phenotypic features of SS.⁵⁶ It is not considered a pathognomonic

Fig. 138.10 Calculation of the focus score. The surface area of all salivary gland lobules in a tissue section is measured with a calibrated microscope eyepiece graticule (a). The foci in the tissue section adjacent to normal-appearing acini are then counted. One such focus is evident in panel b. The total number of foci in the tissue section is then divided by the total surface area of the glandular tissue to yield the number of foci per square millimeter. This number is then multiplied by 4 to derive the focus score, that is, the number of foci per 4 mm² of glandular tissue in the section.

finding and thus must be interpreted in the context of other phenotypic features.

Sclerosing chronic sialadenitis is a histopathologic pattern subject to misinterpretation as being indicative of SS.⁵⁶ It is characterized by acinar atrophy, duct dilation and hyperplasia, and interstitial fibrosis and occurs as a consequence of aging or ductal obstruction. Chronic inflammation is often present, either focally (but not adjacent to normal-appearing acini) or diffusely.

DIFFERENTIAL DIAGNOSIS

Symptomatic dryness of the eyes or mouth is most commonly caused by drugs with anticholinergic effects. Dry eye disease is often idiopathic.⁵⁷ Salivary gland dysfunction may arise from past irradiation of the head and neck, human immunodeficiency virus infection, graft-versus-host disease, uncontrolled diabetes mellitus, and sarcoidosis. Hepatitis C can be associated with a clinical syndrome indistinguishable from primary SS, although these patients are older and have a higher prevalence of cryoglobulinemia, RF and hypocomplementemia and a lower prevalence of anti-SSA and anti-SSB antibodies.⁶³

PATHOGENESIS

SS is mediated by the interaction of incompletely defined genetic, epigenetic, and environmental factors that induce immune dysregulation, loss of self-tolerance, and the development of overt autoimmune disease. SS is heterogeneous in terms of both clinical expression and severity, which implies the predominance of distinct pathogenic pathways in patient subsets.

Genetic susceptibility

The major histocompatibility complex (MHC) class II genes, mainly HLA-DQ and HLA-DR, are the best documented risk factors, with the DR2 and DR3 haplotypes at the DRB1 locus in white populations being the most replicated.⁶⁴ DR2 and DR3 associations are strongest in SS patients with anti-SSA and anti-SSB antibodies,⁶⁵ thus suggesting that specific MHC alleles influence which protein epitopes are targeted by the immune system.

Genes outside the MHC locus also influence susceptibility to SS. Single nucleotide polymorphisms (SNPs) have been identified in genes involved in the innate and adaptive immune response pathways.⁶⁴ The odds ratios for these associations are modest, which suggests that dysregulation of multiple pathways is necessary to precipitate disease. Polymorphisms in genes of the interferon (IFN) pathways have received particular attention because of overexpression of IFN-inducible genes in SS patients.⁶⁶⁻⁶⁸ SNPs in the transcription factors interferon regulatory factor 5 (IRF5) and signal transducer and activator of transcription 4 (STAT4) have been reproducibly associated with SS.⁶⁹⁻⁷¹ IRF5 is activated by Toll-like receptor (TLR) ligation and drives the production of IFN- α and proinflammatory cytokines.⁷² STAT4 is activated by type I IFN, interleukin-12 (IL-12), and IL-23 and stimulates the production of IFN- γ and IL-17.⁷³ The IRF5 and STAT4 risk alleles have

an additive effect on susceptibility to SS, thus highlighting a potential for IFN- or type 17 helper T cell (Th17)-mediated pathogenesis.⁷¹ SNPs in genes involved in B-cell regulation such as BLK may also contribute to susceptibility to SS.⁷⁴

Environmental factors

The first signs of SS typically occur long before diagnosis, thereby impeding study of its etiology. Autoantibodies can precede the development of SS, as evidenced in part by the study of asymptomatic mothers of children with neonatal lupus who have high-titer anti-SSA or anti-SSB antibodies (or both). These mothers are at an increased risk for SS; however, the fact that SS develops in only a minority indicates that autoantibodies alone are insufficient for induction of disease.⁷⁵

Viruses have been postulated as etiologic agents of SS. In this scenario the host immune response is initially directed against persistently infected cells but becomes misdirected toward host tissues because of chronic antigen exposure, thereby resulting in autoimmunity. Support for this theory stems in part from the nature of the targeted autoantigens. Ro52 is induced by IFNs that are produced at high level during viral infection, and enhanced autoantigen expression in tissues may trigger an autoimmune response.⁷⁶ Complexes of La and RNA encoded by Epstein-Barr virus have been shown to induce TLR activation and type I IFN production.⁷⁷ Similarly, Ro60 can bind RNA, and immune complexes containing this bound Ro60 induce type I IFN production,⁷⁸ thus suggesting a link between autoantibodies and expression of IFN-regulated genes in SS tissues.

The predominance of SS in women during or after menopause, as estrogen levels are declining, points to a potential role for sex hormones in development of the disease. Low serum concentrations of dehydroepiandrosterone and dihydrotestosterone have been demonstrated,⁷⁹ which argues for a protective role of androgens in the development of SS.

Effector pathways

A number of inflammatory pathways have been implicated in the pathogenesis of SS. Interactions between these pathways may be important for sustaining the inflammatory process characteristic of SS and may represent important points of intervention. The putative roles of such pathways in the pathogenesis of SS are highlighted in the following sections (Fig. 138.11).

B cells and B cell-activating factor

B cells dominate the larger lymphoid infiltrates¹¹ and may form organized GC-like structures in the salivary glands of patients with SS. These structures contain segregated T- and B-cell zones, follicular dendritic cell networks, and high endothelial venules characteristic of secondary lymphoid organs.⁸⁰ Their presence suggests that local salivary gland antigens drive the hyperactive B-cell response and formation of high-affinity autoantibodies. Activation-induced cytidine deaminase, an enzyme required for immunoglobulin (Ig) heavy-chain class-switch recombination and affinity maturation, is expressed in ectopic GC-like structures, thus implying that autoantibodies are generated in glandular tissues.⁸¹ Evidence of restricted Ig

Fig. 138.11 (1) Self-antigens released via exosomes or the apoptotic cell death of salivary epithelial cells undergo endocytosis by dendritic cells (DCs) with subsequent processing and presentation on the cell surface for recognition by T cells. (2) Autoreactive T cells are activated by DCs expressing self-antigens and secrete proinflammatory cytokines, including interleukin-17 (IL-17) and interferon- γ (IFN- γ). (3) IFN- γ enhances antigen presentation by DCs and induces the expression of B cell-activating factor (BAFF) by salivary epithelial cells. (4) BAFF induces the proliferation of autoreactive B cells and supports differentiation into autoantibody-secreting plasma cells. (5) Autoantibodies form immune complexes with autoantigens bound to nucleic acids derived from cellular debris, which (6) can co-ligate Fc receptors and Toll-like receptors (TLRs) on plasmacytoid DCs (pDCs) and induce IFN- α production. (7) IFN- α induces autoantigen expression in epithelial cells and promotes DC activation, T-cell survival, and plasma cell differentiation and autoantibody production. Th17, type 17 helper T cell.

light-chain gene use and somatic hypermutation of Ig heavy-chain genes in infiltrating B cells further supports this notion.^{82,83}

The potent B-cell survival factor B cell-activating factor (BAFF) may drive B-cell hyperactivity.⁸⁴ BAFF levels are increased in SS serum and saliva and correlate with the level of serum autoantibodies.⁸⁵ BAFF is expressed in large amounts by B and T cells infiltrating SS salivary glands,^{86,87} and BAFF levels have been shown to correlate directly with the extent of lymphocytic infiltration and the presence of ectopic GCs. Overexpression of BAFF and subsequent signaling through its receptor on all mature B cells may enhance the proliferation and survival of autoreactive B cells in salivary glands.

Interferons

Type I IFN, which can be produced by all nucleated cells, and type II IFN (IFN- γ), which is produced by activated T and natural killer cells, have evident roles in the pathogenesis of SS. The association of gene polymorphisms in the IFN pathways with susceptibility to SS and the expression of IFNs and IFN-inducible genes (the “IFN signature”) in both peripheral blood mononuclear cells⁶⁶ and labial salivary gland biopsy specimens from patients with SS^{67,68} strongly implicate IFNs in this process. The enrichment of professional type I IFN-producing plasmacytoid dendritic cells (pDCs) in SS tissues⁷⁸ and the evidence that immune complexes containing self-antigens can stimulate type I IFN production by pDCs via TLR ligation⁸⁸ provide a potential mechanistic link between antibody responses and the IFN signature seen in tissues. Furthermore, co-localization of type I and

type II IFN responses in the same regions of salivary glands⁸⁹ suggests reinforcing interactions between the two pathways. For instance, IFN- γ can enhance signaling through TLRs,⁹⁰ thereby potentially enhancing type I IFN responses.

Once produced, IFNs have the capacity to modulate innate and adaptive immune responses.⁹¹ In addition to upregulating MHC and co-stimulatory molecules, IFNs have the ability to promote B-cell differentiation and antibody production, enhance T-cell survival, and induce the maturation of antigen-presenting cells. IFN- γ can also drive the formation of ectopic GCs⁹² and the expression of BAFF.⁹³ If left unchecked, the normal physiologic effects of IFN may drive the immune dysregulation of SS.

T cells

The strong association of SS with specific MHC alleles implies an important role for T cells. The majority of infiltrating T cells are CD4+, and T-cell infiltrates can be oligoclonal,^{11,94} which is suggestive of an antigen-driven immune response. However, it remains unclear whether T cells are directly cytotoxic in salivary glands. IFN- γ , produced by activated T cells, has been shown to induce salivary dysfunction in several *in-vitro* systems.^{95,96} Proinflammatory IL-17-expressing CD4+ T cells, or Th17 cells, have been identified in SS glands,⁹⁷ and IL-17 expression correlated with higher focus scores.⁹⁸

Role of the target tissue

The primary autoantigens targeted in SS are ubiquitous proteins. Therefore, the specific targeting of exocrine glands implies that the tissues are active participants in the disease process, with damage specifically being focused onto themselves. It is likely that the target tissue supplies the antigens that drive the disease process. Whether this is through the release of autoantigens following apoptotic cell death⁹⁹ or the formation of autoantigen-containing exosomes¹⁰⁰ is unclear.

The theory of “autoimmune epitheliitis”¹⁰¹ is based on observations that SS salivary gland epithelial cells express many of the requisite molecules for antigen presentation and immune activation, including MHC class I, MHC class II, and the T-cell co-stimulatory molecules CD80 and CD86, as well as intercellular adhesion molecule 1, vascular cell adhesion molecule, and CD40. Importantly, the characteristics of activation persist in long-term cell culture. It remains unclear whether these characteristics represent intrinsic functional changes in the salivary epithelium or are a consequence of chronic cytokine stimulation and whether these cells present antigens *in vivo*.

Lymphomagenesis

Malignant transformation is probably driven by antigen. Analysis of Ig genes from MALT lymphoma demonstrates restricted heavy- and light-chain gene use, with evidence of class switching and somatic hypermutation¹⁰² that probably occur in ectopic GC-like structures as a result of chronic antigenic stimulation.¹⁰³ BAFF may play a significant role in this process. Upregulation of the antiapoptotic protein Bcl-2 by BAFF has been shown to promote survival of non-Hodgkin lymphoma cells *in vitro*, and *in vivo*, BAFF levels correlate with tumor severity.

MANAGEMENT

Glandular manifestations

Lacrimal and salivary gland dysfunction is managed both topically and systemically.¹⁰⁴ Patients should maintain adequate hydration; avoid hot, dry, and windy environments; and stop smoking cigarettes. Any drugs being used that have anticholinergic side effects should be reconsidered.

For mild dry eye disease, use of preserved artificial tears up to four times per day may suffice. For more severe disease, preservative-free artificial tears should be instilled more than four times per day and a topical gel or ointment applied at bedtime. Suppression of ocular inflammation can be achieved with short courses of topical steroids, prolonged use of topical cyclosporine (0.05%), and nutritional supplementation with flaxseed oil. Punctal plugs or cauterization will preserve existing tears, and systemic secretagogues may augment tear volume. Additional measures include autologous serum tears, scleral prostheses, moisture goggles, and rarely surgery (such as partial tarsorrhaphy). Blepharitis, if present, should be treated with lid hygiene and compresses, as well as systemic tetracyclines.

Vigorous management of salivary hypofunction alleviates the symptoms of dry mouth and prevents dental caries and oral infections. Many patients choose to sip water or sugar-free fluids. Carbonated beverages should not

be used for this purpose because prolonged exposure of the teeth to an acidic oral environment promotes loss of dental mineral. Secretion of saliva can be stimulated by chewing sugar-free gum or sucking on sour sugar-free candy or xylitol-containing lozenges. Saliva replacement and oral lubrication can be achieved with artificial saliva, sprays, and gels. The M3R agonists pilocarpine and cevimeline increase salivary flow rates and improve symptoms of oral and ocular dryness. Side effects of sweating, nausea, and increased urinary frequency may hinder higher-dose or long-term use. These drugs are contraindicated in patients with uncontrolled asthma, narrow-angle glaucoma, and iritis.

Brushing teeth at least twice per day, flossing daily, and avoiding cariogenic food help prevent dental caries. The use of prescription-strength fluoride toothpaste combined with professional fluoride treatment at 3- to 6-month intervals is standard of care for those at high risk for the development of caries.¹⁰⁵ Dental checkups every 3 to 6 months allow control and removal of dental plaque, early detection of caries, and topical application of fluorides. Concomitant therapy with calcium and phosphate remineralizing agents may be helpful for severe salivary hypofunction.

Treatment of oral candidiasis requires topical application of antifungal agents if flow of saliva is insufficient to bring systemic antifungal drugs to the oral cavity. Most topical antifungal agents have a high sugar content (e.g., nystatin oral suspension) and thus should be avoided because they may promote dental caries. Options include the use of nystatin vaginal tablets, miconazole buccal tablets, or nystatin troches compounded with artificial sweeteners. Dentures should be cleansed nightly.

Oral immunomodulating or immunosuppressive medications have not been found to improve glandular function in controlled trials. Hydroxychloroquine, methotrexate, D-penicillamine, and mycophenolate have also had disappointing results in open trials. Long-term use of oral corticosteroids has not been shown to alter disease-associated decreases in salivary flow rates.¹⁰⁶ Corticosteroids can be effective in treating parotid gland swelling, but their side effects often preclude long-term use.

Biologic agents have the potential to be clinically efficacious in patients with SS based on their targeting of specific immune pathways and their remarkable success in certain other rheumatic diseases. The tumor necrosis factor (TNF) antagonists infliximab and etanercept did not show benefit in short-duration placebo-controlled trials.^{107,108} Rituximab may augment salivary flow in patients with preserved gland function at baseline.¹⁰⁹ In a double-blind, randomized, placebo-controlled trial, rituximab was successful in depleting peripheral blood B cells and augmenting salivary flow at 5 and 12 weeks after the infusion, but not at 48 weeks, the end of the trial.¹¹⁰ Sequential parotid gland biopsy specimens did show histologic improvement at the 12-week time point, with a reduction in the lymphocytic infiltrate, partial disappearance of GCs, and a decrease in lymphoepithelial lesions.¹¹¹ Rituximab was effective in relieving marked salivary and lacrimal gland swelling in a retrospective review.¹¹²

Vaginal dryness and dyspareunia are treated with vaginal lubricants and moisturizers. Postmenopausal vaginal atrophy responds to vaginal estrogen creams. The external vulvar surface may be treated with lubricating creams and vitamin E oil.

Extraglandular manifestations

Treatment of most extraglandular manifestations involves a hierarchy of treatments starting with those appropriate for milder disease and ending with those for more severe disease.¹⁰⁴ Arthritis is initially treated with hydroxychloroquine with or without nonsteroidal antiinflammatory agents.

More severe disease may require low-dose corticosteroids, methotrexate, leflunomide, TNF antagonists, or rituximab. Fatigue is generally treated in a multidisciplinary fashion, with attention to concomitant depression, fibromyalgia, and sleep disorders. Hydroxychloroquine is often prescribed for this indication, and its use is associated with a reduction in the sedimentation rate and immunoglobulin levels, but the clinical impact of this is uncertain. Rituximab showed possible benefit in reducing fatigue in a randomized clinical trial.¹¹³

Distal RTA is treated with bicarbonate or citrate salts to control the acidosis and prevent the formation of renal stones. In patients with impaired renal function or significant proteinuria, a renal biopsy should be performed. The finding of tubulointerstitial nephritis or glomerulonephritis should prompt treatment with a course of corticosteroids.¹⁹ The role of long-term steroid-sparing immunosuppressive agents has not been defined. Cryoglobulinemic glomerulonephritis requires more intensive therapy, often corticosteroids with cyclophosphamide or rituximab.

Interstitial lung disease in SS does not require treatment if forced vital capacity (i.e., >75%) or diffusion capacity (>65%) is not significantly impaired. Corticosteroids are the first-line treatment and may suffice for lymphoid interstitial pneumonia or organizing pneumonia patterns of involvement. Azathioprine, mycophenolate, and cyclophosphamide can be used as steroid-sparing agents, particularly if the lung disease progresses with corticosteroid monotherapy.¹¹⁴

The nonvasculitic peripheral and cranial neuropathies are managed first with tricyclic antidepressants or antiepileptics (e.g., gabapentin, pregabalin, carbamazepine). For patients who fail to respond, intravenous immunoglobulin (0.4 g/kg/day for 5 days) may be beneficial.¹¹⁵ Vasculitic neuropathies are usually treated with corticosteroids and cyclophosphamide, although rituximab is gaining wider acceptance as an alternative to cyclophosphamide.

Cutaneous vasculitis may not require pharmacologic treatment when manifested as mild intermittent purpura. Support stockings and avoidance of prolonged standing may suffice. More severe flares may require moderate-dose corticosteroids, usually in a tapering dose. Hydroxychloroquine, colchicine, dapsone, methotrexate, azathioprine, and mycophenolate mofetil have potential utility in controlling recurrences and minimizing corticosteroid exposure. Rituximab is being used increasingly for control of cryoglobulinemic vasculitis in SS. Cyclophosphamide is reserved for refractory cases or those with more serious manifestations.

Lymphoma

MALT lymphoma localized to the salivary glands may be observed without treatment if asymptomatic.^{116,117} Patients with large parotid gland swelling or other local symptoms may be treated with low-dose involved-field radiotherapy, rituximab alone, or rituximab with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP).¹¹⁷ MALT lymphoma associated with severe extraglandular disease (such as cryoglobulinemia) is treated with rituximab alone at 6-month intervals for up to 2 years or rituximab with CHOP.^{116,117} Disseminated MALT lymphoma is treated with chemotherapy, with or without rituximab.¹¹⁶ Similarly, diffuse large B-cell lymphoma is best treated with rituximab and CHOP.¹¹⁶

Antiphospholipid syndrome: overview of pathogenesis, diagnosis, and management

■ MUNTHER A. KHAMASHTA ■ MARY-CARMEN AMIGO

- Antiphospholipid syndrome (APS) is a disorder of recurrent vascular thrombosis and/or pregnancy losses associated with persistently elevated levels of antiphospholipid-protein antibodies.
- APS is classified as “primary” when there is no underlying disease and “secondary” in the presence of systemic lupus erythematosus or other autoimmune disorder.
- Long-term anticoagulation is used to prevent recurrent thrombosis.
- Recurrent pregnancy loss may be prevented by treatment with subcutaneous heparin and low-dose aspirin during pregnancy.

ANTIPHOSPHOLIPID SYNDROME: DEFINITION AND HISTORY

Antiphospholipid syndrome (APS) is an autoimmune multisystemic disorder characterized by recurrent arterial and venous thrombosis and/or pregnancy morbidity associated with the presence of persistent antiphospholipid antibodies (aPLs). aPLs are a heterogeneous group of antibodies directed against anionic phospholipids or protein-phospholipid complexes. Laboratory tests to identify aPL includes solid-phase immunoassays (enzyme-linked immunosorbent assay [ELISA]) to detect anticardiolipin (aCL) and anti- β_2 -glycoprotein I (anti- β_2 -GPI) antibodies and functional assays to detect the so-called lupus anticoagulants (LACs) that demonstrate the ability of aPL to prolong phospholipid-dependent clotting reactions.¹ The term *lupus anticoagulant* is a misnomer. The LAC phenomenon results in prolonged plasma clotting times; however, patients with LAC are subject to thrombosis, not to hemorrhage, except in uncommon cases such as in hypoprothrombinemia-LAC syndrome.

Although initially described in patients with systemic lupus erythematosus (SLE), APS was soon recognized also to occur in patients without underlying autoimmune disease. APS was then classified as “secondary” in the presence of SLE and “primary” in the absence of SLE or other autoimmune disorders.

Primary APS is the most common cause of acquired thrombophilia and accounts for 15% to 20% of all episodes of deep vein thrombosis with or without pulmonary embolism, one third of new strokes occurring in patients younger than age 50, and 10% to 15% of women with recurrent fetal loss.² APS also accounts for a significant proportion of thromboembolic disease and recurrent fetal loss in patients with SLE. aPLs are present in 30% to 40% of SLE patients, and 10% to 15% of all SLE patients have clinical manifestations of APS.³ It is now generally accepted that aPLs are the most frequent acquired risk factor for a treatable cause of recurrent pregnancy loss and for pregnancy complications.

In 1999, an international consensus meeting formulated the first classification criteria (known as the *Sapporo criteria*) for patients with APS.⁴ In 2006, these criteria were updated¹ (Box 139.1).

EPIDEMIOLOGY

The presence of aPLs is detected in fewer than 1% of apparently normal individuals and in up to 3% of the elderly population. Patients with syphilis, acquired immunodeficiency syndrome, and other infectious disorders, as well as those with drug-induced aPLs, do not usually have clinical features

of APS. Prospective studies have shown an association between the presence of aPLs and the first episode of venous thrombosis,² the first myocardial infarction,⁵ and the first ischemic stroke.⁶ Antibody profile, isotype, level, and other undefined characteristics of aPLs, as well as underlying disease, may all be determining features in developing the clinical syndrome. It is now recognized that patients with triple aPL positivity, defined as the presence of LAC and high titers of aCL and anti- β_2 -GPI, are at higher risk of thrombosis.^{7,8} Risk stratification for thrombosis in patients with APS is summarized in Table 139.1.

Genetic studies strongly support a genetic basis for disease in families with APS, which suggests an autosomal dominant mode of inheritance. An association with HLA-DR7, DR4, DRw53, DQw7, and C4 null alleles has been reported.⁹

PATHOGENESIS

There is evidence that aPLs can be pathogenic rather than a simple serologic marker for APS. Multiple molecular pathways are implicated in the pathogenesis of APS.

Mechanisms of thrombosis

Despite the persistent presence of aPLs in circulation, thrombotic events occur only occasionally in patients with aPLs, which suggests that the presence of aPLs is necessary but not sufficient for clot formation *in vivo*. The “two-hit hypothesis” has been proposed, which holds that aPLs (first hit) can exert their prothrombotic action only in the presence of another thrombophilic condition (second hit).¹⁰

The aPL interaction with endothelial cells, monocytes, and platelets induces a prothrombotic and proinflammatory phenotype. A growing body of evidence shows that complement activation is a critical early mediator in APS by linking aPLs to thrombosis and fetal injury.¹¹

Additionally, interaction of aPLs with proteins implicated in clotting regulation such as prothrombin, factor X, protein C, protein S, and plasmin may interfere with the inactivation of procoagulant factors and fibrinolysis¹² (Box 139.2).

Mechanisms of pregnancy loss

The pathogenesis of obstetric APS remains uncertain. Intraplental thrombosis was initially suggested to be the main pathogenic mechanism of fetal loss. However, in observational studies of women with obstetric APS not all placentas examined showed placental thrombosis, infarctions, or vasculopathy. *In vitro* studies demonstrated that aPLs may impair trophoblastic invasion and human chorionic gonadotropin production, promoting not only early miscarriages but also fetal loss and uteroplacental insufficiency.¹³ Recent advances have proposed that complement, β_2 -GPI, and annexin V play a central role in fetal loss¹⁴ (Box 139.3).

CLINICAL FEATURES

Overview

APS is the most common cause of acquired thrombophilia. Recurrent thromboses and pregnancy morbidity are the hallmarks of the syndrome. However, thrombocytopenia or hemolytic anemia may occur as the sole manifestation.

BOX 139.1 PRELIMINARY CRITERIA FOR CLASSIFICATION OF ANTIPHOSPHOLIPID SYNDROME**Clinical criteria****Vascular thrombosis**

One or more clinical events of arterial, venous, or small-vessel thrombosis in any tissue or organ. Thrombosis must be confirmed by Doppler ultrasonography, other imaging, or histopathologic analysis, with the exception of superficial venous thrombosis. The histopathologic study does not have to demonstrate significant evidence of inflammation of the blood vessel.

Pregnancy morbidity

- One or more unexplained deaths of morphologically normal fetuses at 10 or more weeks of gestation, with a normal fetal morphology confirmed by ultrasound or direct examination of the fetus.
- One or more premature births of a morphologically normal newborn at 34 weeks of gestation or before due to
 - Severe preeclampsia or eclampsia defined according to current standards, or
 - Recognized placental insufficiency
- Three or more consecutive spontaneous abortions without explanation before 10 weeks of gestation, excluding those associated with hormonal or anatomic alterations in the mother or chromosomal alterations inherited from either parent.

Laboratory criteria

The presence of at least one of the following test results:

- Lupus anticoagulant in the plasma on two or more separate occasions within a period of 12 weeks, detected according to the guidelines of the International Society of Thrombosis and Haemostasis (Scientific Subcommittee on lupus anticoagulant/phospholipid-dependent antibodies).
- IgG or IgM anticardiolipin antibodies in plasma or serum in medium-high titers (more than 40 GPL or MPL units, respectively) on two or more separate occasions within a period of 12 weeks, as measured by standardized ELISA.
- IgG or IgM anti- β_2 -glycoprotein I antibodies in the serum or plasma (in titer above the 99th percentile) on two or more separate occasions within a period of 12 weeks, as measured by standardized ELISA according to recommended procedures.

ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin.

BOX 139.2 MECHANISMS OF THROMBOSIS IN ANTIPHOSPHOLIPID SYNDROME

- Interaction between antiphospholipid antibodies and cells (endothelial cells, monocytes, platelets)
- Activation of cell signaling pathways
- Transcription of procoagulant factors (tissue factor) and adhesion molecules
- Complement activation
- Impaired nitric oxide production
- Antiphospholipid antibody inactivation of fibrinolysis

BOX 139.3 MECHANISMS OF PREGNANCY LOSS IN ANTIPHOSPHOLIPID SYNDROME

- Intraplental thrombosis
- Impaired trophoblastic invasion and hormone production
- Activation of the complement system
- Defective placentation due to interference of anti- β_2 -glycoprotein I with trophoblast growth and differentiation
- Displacement of annexin A5 by immunoglobulin G antiphospholipid antibody- β_2 -glycoprotein I complexes

TABLE 139.1
Risk stratification for recurrent thrombosis in patients with antiphospholipid syndrome

	High risk	Low risk
Serologic profile	LAC positivity Triple positivity (LAC + aCL + anti- β_2 -GPI) Isolated persistent positivity for aCL (medium-high titers)	Isolated intermittent positivity for aCL or anti- β_2 -GPI at low titers (<40 GPL or MPL units)
Clinical profile	Presence of systemic lupus erythematosus Coexistent cardiovascular risk factors History of arterial thrombosis Recurrent thrombosis (arterial, venous, or both) despite anticoagulant therapy	Previous single venous thrombosis (particularly in association with transient risk factors)

aCL, anticardiolipin; β_2 -GPI, β_2 -glycoprotein I; LAC, lupus anticoagulant.
Adapted from Les I, Ruiz-Irastorza G, Khamashta M. Intensity and duration of anticoagulation therapy in antiphospholipid syndrome. *Semin Thromb Hemost* 2012;38:339-47.

Any organ can be affected in this disorder, thus the range of clinical features is extremely wide.¹⁵

Some patients who have features of APS alone at presentation later develop features typical of SLE.¹⁶ Conversely, patients with SLE may develop APS some time after the onset of SLE.

Arterial and venous thromboses, which may affect large, medium-sized, or small vessels, are among the main features of APS. In contrast, thromboses associated with congenital thrombophilias (protein C, protein S, factor V Leiden, and factor II 20210A mutations and antithrombin deficiency) are

REPORTED SITES OF VENOUS THROMBOSIS IN PATIENTS WITH APS

Fig. 139.1 The deep and superficial veins of the legs are the most frequently reported sites of thrombosis in patients with antiphospholipid syndrome (APS).

almost exclusively venous. Histologic studies of the vascular lesion have shown thrombus without inflammatory infiltrates.¹⁷ In some cases, the vessel wall exhibits marked medial hyperplasia and severe luminal narrowing, the so-called APS vasculopathy.¹⁸

Other features including thrombocytopenia, Coombs-positive hemolytic anemia, abnormalities of cardiac valves, nonthrombotic skin lesions, and a variety of nonthrombotic central nervous system abnormalities are less clearly associated with a specific pathophysiologic mechanism.

Venous thrombosis

In the venous circulation, the deep veins of the lower extremities are the most frequent sites of thrombosis (Fig. 139.1). Reports of pulmonary hypertension caused by either recurrent pulmonary emboli or *in-situ* thrombosis are rare. Other reported sites of venous thrombosis include the pelvic, renal, mesenteric, portal, hepatic, axillary, ocular, and sagittal veins, as well as the inferior vena cava. Venous events usually occur at single sites with a tendency to recur in the same vascular bed as the original thrombotic episode.

Arterial thrombosis

Arterial thromboses are a major feature of APS. Arterial occlusions can affect the vascular tree from the aorta to the small capillaries. Ischemic stroke or transient ischemic attacks (TIAs) are the most common presentation of arterial thrombosis (Fig. 139.2).

Other arterial sites, including retinal, coronary, brachial, mesenteric, and peripheral arteries, are also subject to thrombosis.

Patients with APS who experience arterial thrombosis have been found to be at high risk of recurrence. The prognostic implications of these findings are significant, because ischemic stroke is the most common arterial manifestation of APS and a major cause of morbidity and mortality.¹⁹ There should be a high level of suspicion of APS in young patients who have no risk factors for atherosclerosis.

Pregnancy complications

Pregnancy loss, fetal distress, and premature birth are frequent complications in women with APS. Pregnancy loss can occur at any stage of gestation, particularly during the second and third trimesters (about 50% of cases). This differs from the pattern of pregnancy loss in the normal population, in which pregnancy loss usually occurs during the first trimester and is most often caused by morphologic or chromosomal abnormalities. It is

Fig. 139.2 In patients with antiphospholipid syndrome (APS) the intracranial arteries are the most frequently reported sites of thrombosis, which results in stroke and transient ischemic attacks. Myocardial infarction, gangrene of the fingers and toes, and bowel infarction have all been described and are presumed to be secondary to thrombotic occlusion of arteries supplying these sites. In some instances, occlusion of intracranial arteries may be secondary to emboli from heart valve vegetations.

not possible to predict which women who test positive for aPLs will develop complications in pregnancy. However, an adverse previous obstetric outcome, a history of thrombosis, and triple positivity for LAC, aCL, and anti- β_2 -GPI antibodies have been identified as predictors of high risk.^{20,21} Low-titer positivity for immunoglobulin G (IgG) aCL and IgM- or IgA-positive test results seem to be less frequently associated with pregnancy complications.

In APS, thrombotic occlusion of placental vessels and placental infarction are frequently reported. In some instances, however, the extent of placental damage does not appear to be sufficient to account for the degree of fetal distress. The aborted fetus usually appears normal. Although some babies born to mothers with APS may test positive for aCL, complications in neonates because of these antibodies are unusual.

The potential complications of pregnancy in women with APS also include preeclampsia, HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), placental insufficiency, intrauterine growth restriction, abruptio placentae, and premature delivery. In addition, pregnant women with APS may experience thrombosis and complications due to treatment. Women with purely obstetric APS are at high risk of thrombotic complications during follow-up.²²

Nervous system abnormalities

Stroke and TIA are the most frequent neurologic complications of APS.²³ Because emboli from heart valve vegetations may be responsible for cerebral ischemia, echocardiography should be performed on patients with APS who experience TIA or stroke.

Cerebral ischemia may be silent, and when multiple events occur (Fig. 139.3) patients may first experience symptoms such as seizure or cognitive dysfunction. Without anticoagulant therapy, strokes may recur and patients occasionally have multiinfarct dementia at presentation. Magnetic resonance imaging (MRI) may show changes that vary from single lesions to multiple hyperintense white matter lesions (Fig. 139.4). Cerebral venous sinus thrombosis has occasionally been reported.

Ocular ischemic events and occlusion of retinal veins can occur.²⁴ Sensorineural hearing loss, presenting as sudden deafness has been associated with aPL.²⁵ Many other neurologic abnormalities not clearly linked to thrombosis include seizures, transverse myelopathy, chorea, Guillain-Barré syndrome, psychosis, and migraine headaches. APS and multiple sclerosis can be difficult to distinguish. A careful history taking, the localization of the lesions on MRI, and the response to anticoagulant therapy may be helpful in the differential diagnosis of these very different diseases.²⁶

Cardiac valve abnormalities

Valvular involvement has a prevalence of more than 80% if highly sensitive techniques such as transesophageal echocardiography are used.²⁷ Left-side valves, especially the mitral valve, are the most frequently involved. Echocardiographic findings include valve thickening, nodules, and vegetations (Fig. 139.5). The valve lesions in APS may be hemodynamically nonsignificant or may lead to valvular regurgitation or stenosis. Mitral regurgitation is reported in some series to occur in up to 25% of patients. Despite this high prevalence, only 4% to 6% of aPL-positive patients with valve disease will require surgical treatment.²⁸ It has been suggested that heart valve disease should be included as a classification criterion for APS.

Fig. 139.3 Demonstration by magnetic resonance imaging of biparietal infarctions in a 26-year-old woman with antiphospholipid syndrome. This woman also had a right frontal lobe infarct, which is not shown here. She had no risk factors for thrombosis other than positivity for the lupus anticoagulant and high-positive results on assays for immunoglobulin G anticardiolipin antibodies. Her first pregnancy ended in intrauterine fetal death at 24 weeks' gestation.

Skin manifestations

Skin manifestations associated with APS include livedo reticularis (LR), leg ulcers, cutaneous necrosis, gangrene of the digits or extremities, superficial thrombophlebitis, necrotizing purpura, anetoderma, and nail-fold infarcts.²⁹ None of these manifestations is pathognomonic of APS. LR is the most common skin manifestation of APS. LR can be a marker of a high risk of arterial events.³⁰ LR may occur in patients with a variety of other disorders, including connective tissue diseases, vasculitides, multiple cholesterol emboli syndrome, sepsis, hyperoxaluria, and Sneddon syndrome (in which it is associated with stroke), as well as in normal individuals.

Different types of skin ulcerations may be observed.³¹ Some ulcers tend to occur in the pretibial area and ankle (Fig. 139.6). Large ulcers may resemble pyoderma gangrenosum. The latter should also be distinguished from postphlebotic ulcers, which can occur in patients who have had multiple episodes of deep vein thrombosis in the same leg.

Cutaneous gangrene and nail-fold infarcts are usually consequences of thrombosis of small arteries.

Fig. 139. 4 Demonstration by magnetic resonance imaging of multiple hyperintense lesions in a 34-year-old woman with positivity for lupus anticoagulant, pregnancy losses, history of a transient ischemic attack, depression, and cognitive dysfunction.

Thrombocytopenia and hemolytic anemia

Thrombocytopenia is a well-recognized feature of APS³² occurring in 16% to 46% of patients. Platelet levels fluctuate in the range of 100 to 150×10^3 per mm^3 and are seldom low enough to be associated with hemorrhage (less than 50×10^3 per mm^3).

The pathogenesis of thrombocytopenia in APS is unclear. Hypotheses include binding of aPLs to platelet membrane phospholipids, β_2 -GPI-phospholipid complexes, and coexisting antibodies to platelet membrane glycoproteins.

Patients with aPLs and hemocytopenias who have no history of thrombosis or pregnancy morbidity are not classified as having APS. However, this combination of findings may indeed represent a pre-thrombotic state that precedes the onset of APS ("hematologic APS"), and it has been suggested that thrombocytopenia be incorporated into the clinical criteria for APS.³³

About 10% to 20% of patients with APS have a positive Coombs test result, but hemolytic anemia is relatively uncommon. The simultaneous occurrence of hemolytic anemia and thrombocytopenia, referred to as *Evans syndrome*, is a rare occurrence in series of patients with APS.

Renal manifestations

Thrombotic microangiopathy is the most characteristic finding in APS nephropathy, although it is not associated exclusively with this syndrome. It is characterized by the triad of hypertension, proteinuria, and renal failure. Fibrous intimal hyperplasia, focal cortical atrophy, and arterial occlusions have also been described.³⁴ Refractory hypertension secondary to renal artery stenosis can be also seen.³⁵

Fig. 139. 6 Large leg ulcers resembling pyoderma gangrenosum in a 55-year-old woman with antiphospholipid syndrome and a history of gangrene requiring amputation of several toes, splinter hemorrhages, mitral valve nodules, and persistent positivity for lupus anticoagulant.

Fig. 139. 5 Two-dimensional transthoracic echocardiogram (left) and color Doppler echocardiogram (right) of a patient with antiphospholipid syndrome. There is nodular thickening of both mitral leaflets. The left atrium is dilated and mitral stenosis is apparent.

Catastrophic antiphospholipid syndrome

Catastrophic antiphospholipid syndrome (CAPS) is a potentially life-threatening condition characterized by thrombosis at multiple organ sites occurring concurrently or over a short period of time in association with positive results on aPL tests. Even though fewer than 1% of APS patients develop this complication its potentially lethal outcome emphasizes its importance. Ischemia of the kidneys, bowels, lungs, heart, and/or brain is most frequent, and in rare cases adrenal, testicular, splenic, pancreatic, or skin involvement has been seen. Occlusion of small vessels (thrombotic microangiopathy) is characteristic, resulting in symptoms related to dysfunction of the affected organs.³⁶ Depending on the organs involved at presentation patients may have hypertension and renal impairment, acute respiratory distress syndrome, alveolar hemorrhage and capillaritis, confusion and disorientation, abdominal pain and distention secondary to bowel infarction, or multiorgan failure.

Unless the condition is considered in the differential diagnosis, it may be missed, which results in a disastrous outcome for these patients. CAPS must be distinguished from thrombotic thrombocytopenic purpura and disseminated intravascular coagulation.

LABORATORY DIAGNOSIS

Serologic assays used in the diagnosis of antiphospholipid syndrome

Anticardiolipin test

The aCL assay is simple and sensitive and provides helpful information to aid in the diagnosis of APS. This test uses the ELISA technique to detect antibody binding to solid plates coated with either cardiolipin or other phospholipids (Table 139.2). An aCL titer of more than 40 GPL units has been associated with an increased risk of thrombosis. The IgG isotype appears to be more closely associated with clinical manifestations than either the IgM or IgA isotype.³⁷

More specific serologic assays for antiphospholipid syndrome

It has been shown that β_2 -GPI is a relatively specific antigen for autoantibodies present in APS patients.³⁸ Anti- β_2 -GPI positivity has been reported to be associated primarily with thrombosis in patients with APS, but also with pregnancy loss and other manifestations of APS.³⁹

Domain I of β_2 -GPI is an integral component in the pathogenicity of this protein.⁴⁰ The interaction of β_2 -GPI with phospholipids induces major conformational change in this protein that exposes hidden epitopes within domain I. Anti- β_2 -GPI with specificity to domain I (anti-Dm I) increases susceptibility to thrombosis, and high titers are present in patients with triple positivity, which highlights its association with high risk of thrombosis.⁴¹

TABLE 139.2
Current assays used to confirm the diagnosis of antiphospholipid syndrome

Assay	Method
Criteria aPL assays	
Anticardiolipin	ELISA
Anti- β_2 -glycoprotein I	ELISA
Lupus anticoagulant	Clotting/functional assays
Noncriteria aPL assays	
Assays to detect antibodies to other phospholipids (e.g., phosphatidylserine, phosphatidylinositol, phosphatidic acid, phosphatidylglycerol, phosphatidylethanolamine, phosphatidylcholine)	ELISA
Annexin A5 resistance assay	Clotting/mechanistic assay
Assays to detect antibodies to prothrombin or prothrombin/phosphatidylserine	ELISA
Assays to detect antibodies to clotting proteins (e.g., protein C, protein S)	ELISA

aPL, antiphospholipid antibody; ELISA, enzyme-linked immunosorbent assay.

A number of laboratories include in their test panel assays that detect antibodies directed against other negatively charged phospholipids such as phosphatidylserine, phosphatidic acid, phosphatidylinositol, and phosphatidylglycerol. APS patients may also have antibodies directed against zwitterionic phospholipids such as phosphatidylethanolamine or positively charged phospholipids such as phosphatidylcholine (see Table 139.2). Patients with APS have antibodies that bind proteins other than β_2 -GPI, including prothrombin (PT), protein C, protein S, and annexins.^{42,43} A significant percentage of anti-PT antibodies demonstrate LAC activity. Although LAC is a known thrombosis risk factor, currently available data are inconclusive regarding whether anti-PT antibodies are an independent risk factor for thrombosis.⁴⁴ Novel antibodies to vimentin-cardiolipin complexes may have a potential diagnostic role in patients with clinical manifestations of APS but do not conform to the conventional serologic criteria.^{45,46} The value of these tests remains uncertain.

Lupus anticoagulant test

A positive LAC test result indicates the presence of an inhibitor of coagulation that does not react directly with individual coagulation factors but rather inhibits phospholipid-dependent coagulation reactions, an effect that is not associated with bleeding complications. Although aPLs detected in aCL and LAC tests are specific for phospholipids, phospholipid-binding proteins, or a complex of these molecules, the two tests (aCL and LAC) do not necessarily identify the same antibodies. The LAC test is less sensitive but more specific for detection of aPLs. Guidelines and criteria for the detection of LAC have been formulated and revised.⁴⁷

It is now clear that only some autoantibodies, those directed against domain I of β_2 -GPI, are associated with thromboembolic events.⁴⁸ There is no specific ELISA to detect anti-Dm1 antibodies. However, anti-Dm1 antibodies possess LAC activity. Therefore positivity for anti- β_2 -GPI (by ELISA) and the presence of LAC help identify the pathogenic anti- β_2 -GPI antibodies.⁴⁹

MANAGEMENT

Management of thrombosis

Prevention of thrombosis is a major goal of therapy in patients with aPLs, and treatment considers two different clinical groups: (1) patients with APS who have already experienced a thrombotic event; and (2) aPL carriers without previous clotting, that is, purely asymptomatic individuals, patients with SLE, and women with obstetric APS.

Secondary thromboprophylaxis

At present, antithrombotic therapy remains the main therapeutic approach in APS patients with thrombosis. The remaining two key questions are whether patients with APS should receive the same therapy as the general population with similar manifestations and whether arterial and venous events should be treated in different ways.

Two randomized clinical trials have compared high-intensity anticoagulation (target international normalized ratio [INR], 3.0 to 4.0) with standard anticoagulation (target INR, 2.0 to 3.0) for secondary thromboprophylaxis in patients with APS.^{50,51} Neither study found significant differences in efficacy or adverse effects between the two regimens. However, given the overrepresentation of patients with first venous thromboembolism in both trials, the recommendation to administer warfarin therapy to a target INR of 2.0 to 3.0 can be extended only to that subgroup.

Debate persists regarding treatment of patients with arterial thromboses. The Antiphospholipid Antibodies and Stroke Study (APASS) suggested that patients with stroke and aPL positivity who do not fulfill classification criteria for APS should be treated the same as the general population.⁵² However, it is the authors' view that patients with definite APS who have arterial disease and/or recurrent events merit a more aggressive approach, which might include warfarin treatment with a target INR of more than 3.0 or combined anticoagulant-antiaggregant therapy.⁵³

High-intensity oral anticoagulation therapy carries an inevitable risk of serious bleeding complications. Estimating the risk of bleeding in individual patients may help prevent complications.^{54,55} Recent studies in APS patients have found bleeding rates of 0.8% per year (with treatment to a target INR of 2.0 to 3.0). It should be stressed that the mortality rate due to thrombosis is higher than the mortality rate due to bleeding in patients with APS.^{56,57}

For APS patients who show no response to or poor tolerance to warfarin and for those who refuse to take vitamin K antagonists, long-term treatment

with low-molecular-weight heparin (LMWH) may be a safe and effective alternative to warfarin therapy.⁵⁸

It must be emphasized that concomitant vascular risk factors, which increase the likelihood of thrombosis in patients with aPLs, must be addressed.^{59,60} A consensus document on primary and secondary thromboprophylaxis in individuals with aPLs has been published.⁵⁴

Primary thromboprophylaxis

Retrospective studies suggest that patients with lupus and aPLs will develop thrombosis at an annual rate of around 3% to 4%. Also, women with purely obstetric APS may experience subsequent thromboses at a rate of 3% to 7% per year.⁶¹ The actual risk in healthy asymptomatic carriers of aPLs is probably lower. However, asymptomatic aPL carriers who have an aPL profile considered to place them at high risk of a first vascular event (positivity for LAC, aCL, and anti- β_2 -GPI, or so-called triple positivity) have an incidence of first thrombosis as high as 5.3% per year.⁶²

The presence of circulating aPLs should be considered a thrombotic risk factor, with several other variables modulating the final clinical expression. The most important variables are the aPL profile (type, level, and persistence); the coexistence of other thrombotic risk factors such as hypertension, smoking, hypercholesterolemia, or estrogen use; and the presence of an underlying autoimmune disease^{59,63} (see Table 139.1). Actually, the most important prophylactic measure may be the avoidance or reduction of these modifiable cardiovascular risk factors in all individuals with aPL positivity.

SLE by itself is considered a risk factor for thrombosis. For that reason, all patients with SLE and LAC or with aCLs at medium-high titers should be given primary thromboprophylaxis.⁵⁴ Hydroxychloroquine has been shown to protect against thrombosis in lupus patients, including those with aPLs.⁶⁴ Low-dose aspirin may also be effective in this setting.⁶⁵

Thromboprophylaxis in asymptomatic aPL carriers should be individualized based on the antibody profile. For those individuals with a high-risk profile (LAC or aPL triple positivity), especially in the presence of other thrombotic risk factors, low-dose aspirin therapy is suggested.

Thromboprophylaxis with LMWH in high-risk situations, such as surgery, prolonged immobilization, and the puerperium, is recommended.⁵⁴

PREGNANCY MANAGEMENT

With proper management, more than 70% of pregnant women with APS deliver a viable, healthy infant. Preconceptional counseling is essential to estimate the chance of both fetal and maternal problems. Despite the good prognosis achievable with correct management, patients must be aware that there is an increased risk of serious complications, including miscarriage, fetal death, prematurity, preeclampsia, and thrombosis. Pregnancy should be discouraged in all women with pulmonary hypertension due to the high risk of maternal death and should be postponed in the setting of uncontrolled hypertension or whenever a thrombotic event, particularly stroke, has recently taken place.

General pregnancy care in women with antiphospholipid syndrome

All pregnant women with APS should be cared for by high-risk medical-obstetrical clinics.

The objectives of prenatal care in the second and third trimesters are close observation for maternal complications and fetal surveillance testing. The latter should begin at 32 weeks' gestation, or earlier if the clinical situation raises suspicion of placental insufficiency, and should continue at least weekly until delivery. Uterine and umbilical artery Doppler evaluations are widely used to assess the risk of preeclampsia, placental insufficiency, and fetal growth restriction, with normal examination findings having high negative predictive values.⁶⁶

Pharmacologic management of antiphospholipid syndrome during pregnancy

Preconceptional aspirin therapy is desirable due to its possible beneficial effect on early stages of implantation. Early enthusiasm for treating pregnant women with APS using glucocorticoids waned in the early 1990s when two small, randomized trials found a lack of benefit of glucocorticoid therapy. Also, randomized trials have demonstrated that either the addition of intravenous immunoglobulin (IVIG) to heparin or IVIG alone offers no better outcomes.

For therapeutic purposes during pregnancy, women with APS must be categorized into one of three groups: (1) those with recurrent early

(preembryonic or embryonic) miscarriage and no other features of APS, (2) those with one or more prior fetal deaths (more than 10 weeks' gestation) or prior early delivery (less than 34 weeks' gestation) due to severe preeclampsia or placental insufficiency, and (3) those with previous thrombosis irrespective of pregnancy history.

Recurrent early (preembryonic or embryonic) miscarriage

The use of heparin (LMWH or unfractionated heparin) in combination with low-dose aspirin has been investigated by many groups. Recent expert guidelines recommend the combination of aspirin with either unfractionated heparin or LMWH.⁶⁷ However, the authors believe that the option of monotherapy with aspirin cannot be discarded in this subgroup of women, because observational studies have reported 79% to 100% pregnancy success rates with low-dose aspirin alone in this subgroup of women. One study suggests that women with refractory aPL-related pregnancy losses may have improved pregnancy outcomes with low-dose prednisolone taken until 14 weeks' gestation.⁶⁸ These results warrant further investigation.

Fetal death or prior early delivery due to severe preeclampsia or placental insufficiency

The optimal treatment for women who have experienced prior fetal death (more than 10 weeks' gestation) or prior early delivery (less than 34 weeks' gestation) has not been defined by randomized trials. However, because fetal loss is a more severe and specific manifestation of APS, combination therapy with aspirin and heparin is generally recommended.²⁰ When used for obstetric purposes, aspirin is best started preconceptionally. Either unfractionated heparin or LMWH, in combination with aspirin, can be given and is started once pregnancy has been confirmed. LMWH shows better bioavailability, has a longer half-life, and can conveniently be given once daily.

Antiphospholipid syndrome with thrombosis

For pregnant women with APS who have had a prior thrombotic event, low-dose aspirin and therapeutic-dose heparin or LMWH anticoagulation are recommended.²⁰ Heparin does not cross the placenta and is not known to cause any adverse fetal effects. However, long-term use of heparin in pregnancy has been associated with osteoporosis in the mother. LMWH seems safer in this setting. Vitamin K antagonists are teratogenic and should be avoided between 6 and 9 weeks' gestation. Due to the risk of fetal bleeding thereafter, warfarin should be used after 9 weeks' gestation only in exceptional circumstances.

Postpartum period

Antithrombotic coverage of the postpartum period is recommended in all women with aPLs, with or without prior thrombosis.⁶⁷ Those in the former group need long-term anticoagulation, and the authors prefer switching these patients to warfarin after delivery as soon as they are in clinically stable condition. In patients with no previous thrombosis, the recommendation is for continuation of prophylactic-dose heparin or LMWH, with an extension that varies from 1 to 6 weeks after delivery depending on the presence of additional risk factors.⁶⁹ Both heparin and warfarin are compatible with breastfeeding.⁶⁷

MANAGEMENT OF OTHER MANIFESTATIONS OF ANTIPHOSPHOLIPID SYNDROME

Thrombocytopenia usually does not require intervention. In a minority of cases it can be severe, and corticosteroids are the treatment of choice. Anecdotal reports have shown that low-dose aspirin, dapsone, danazol, chloroquine, IVIG, and warfarin have improved steroid-resistant thrombocytopenia. Splenectomy has been safely and successfully performed in some patients with APS with refractory thrombocytopenia.⁷⁰

Headache has been reported to improve remarkably with low-dose aspirin, and in very resistant cases warfarin may be an alternative.

In some cases valvular damage may result in significant hemodynamic compromise, requiring surgery. Both biologic and mechanical valves have been implanted. Regardless of the valve type used, all patients with APS who have valve prostheses require full anticoagulation. Heart valve surgery is a very high-risk procedure in patients with APS.⁷¹ Bleeding and thrombotic complications are the main causes of morbidity and mortality. Therefore

■ **TABLE 139.3**
Alternative therapies for antiphospholipid syndrome (APS)

Treatment	Target effect (<i>in vitro</i> and/or animal studies)	Results of human studies
Hydroxychloroquine	aPL-induced platelet activation Inhibition of aPL-mediated thrombosis in mice Protection of aPL-induced displacement of annexin A5 from phospholipin bilayers	Decreases thrombotic risk in SLE Increases survival in SLE Protective against thrombosis in aPL+ individuals Decreases aPL and/or LAC in SLE patients
Statins	Reversal of aPL-induced endothelial cell activation and TF upregulation Abrogation of enhanced thrombus formation in mice	Decrease proinflammatory and prothrombotic markers in APS Contraindicated in pregnancy
Rituximab	Blocking of B-cell activating factor, which can prevent disease onset in APS mouse model	Effective for aPL-related cytopenias Effective for catastrophic APS Increases response in APS (off-label use) RITAPS study under way
New oral anticoagulants	Dabigatran: inhibition of thrombin Rivarox: inhibition of factor Xa	No data on efficacy and safety in APS patients
Potential immunomodulatory approaches	Anticomplement peptides Inhibition of TF Inhibition of nuclear factor κ B Inhibition of p38 MAPK Peptides mimicking domains of β_2 -GPI or β_2 -GPI receptor blockers Other B-cell inhibitors	Experimental studies No human data

aPL, antiphospholipid antibody; β_2 -GPI, β_2 -glycoprotein I; LAC, lupus anticoagulant; MAPK, mitogen-activated protein kinase; RITAPS, Rituximab in Antiphospholipid Syndrome; SLE, systemic lupus erythematosus; TF, tissue factor.

strict and coordinated perioperative control of the anticoagulant therapy must be accomplished.

It is important to distinguish the renal thrombotic microangiopathy characteristic of APS from other forms of inflammatory renal damage, mainly in SLE patients. The appropriate treatment with oral anticoagulation or corticosteroids depends on the histologic findings. The presence of aPLs seems to be associated with a poorer prognosis for the transplanted kidney in transplant patients with both SLE-related and primary APS. Post-transplant thromboembolic phenomena, the recurrence of thrombotic microangiopathy in the graft despite anticoagulation, and thrombosis of the graft have all been reported.⁷²

ALTERNATIVE THERAPIES FOR REFRACTORY AND DIFFICULT CASES

In patients with recurrent thrombosis, fluctuating INR levels, major bleeding, or a high risk of major bleeding, long-term therapy with LMWH, hydroxychloroquine, or statins has been suggested (Table 139.3).

Hydroxychloroquine

Hydroxychloroquine use has been associated with lower odds of persistent positivity for aPLs and/or LAC in SLE patients.⁷³

At this time, even though there are insufficient data to recommend hydroxychloroquine for primary and secondary prevention, because of its excellent safety profile it might be reasonable to add hydroxychloroquine to anticoagulant therapy in APS patients who develop recurrent thrombosis despite optimum anticoagulation.

Statins

The pleiotropic effects of statins on inflammation, immunomodulation, and vascular function may support their use in combination with warfarin or aspirin in patients with APS.⁷⁴⁻⁷⁶ Statins have profound effects on monocyte,

lymphocyte, and endothelial cell activity, all of which may contribute to thrombosis prevention in APS patients.⁷⁷

Rituximab

Rituximab (RTX) has been shown to be a good treatment for life-threatening CAPS in a small number of patients. Case reports have described the successful use of RTX in patients with aPLs and autoimmune-mediated thrombocytopenia and hemolytic anemia. The rationale for its use in APS is the proposal that B cells are involved in the clinical manifestations of APS.

A systematic review of the off-label use of biological therapies in systemic autoimmune diseases revealed a high therapeutic response with RTX in patients with APS (92%).⁷⁸ The Rituximab in Antiphospholipid Syndrome (RITAPS) study, an open-label, descriptive pilot study, is currently under way to assess the efficacy and safety of RTX in patients with persistent aPL positivity who show resistance to standard anticoagulant therapy.

New oral anticoagulants

Novel oral anticoagulants, including dabigatran etexilate and rivaroxaban, function by directly inhibiting thrombin and factor Xa, respectively. Both agents have been shown to be effective in the management of venous thromboembolism, and they do not require laboratory monitoring. However, at the present time there are no data on their efficacy and safety in patients with APS.

Future treatments

Understanding the molecular mechanisms triggered by aPLs may help researchers design new alternatives to treat the clinical manifestations of APS. It is likely that the current antithrombotic approach in these patients will be replaced by an immunomodulatory approach in the future.⁷⁹ One example is the successful use of eculizumab, a monoclonal antibody that targets C5a, in a patient with relapsing CAPS⁸⁰ and also its use to prevent the recurrence of CAPS in a patient who underwent renal transplantation.⁸¹

Classification and epidemiology of scleroderma

■ MAUREEN DAVIDICA MAYES ■ SHERVIN ASSASSI

- The incidence (number of new cases each year) of systemic sclerosis (SSc) in the United States is 20 cases per million population.
- Prevalence (total number of cases) of SSc in the United States is estimated at more than 276 persons per million population.
- Clinical subtype (limited versus diffuse disease) and the specific autoantibody present are correlated with disease severity.
- Blacks are affected at a younger age and have more diffuse skin manifestations and more severe lung disease.
- The anticentromere antibody is a marker for limited cutaneous SSc and an increased risk of pulmonary arterial hypertension late in the disease course.
- Presence of the anti-RNA polymerase III antibody is a predictor of more severe skin disease and renal crisis.
- Antibody to topoisomerase I is a marker for interstitial lung disease.
- Multiple genetic variants increase SSc susceptibility and influence outcome.
- Survival appears to have improved in the past decades; the major cause of death is lung involvement.

INTRODUCTION

Scleroderma is usually divided into two forms: *localized scleroderma* (morphea, linear scleroderma, and related syndromes), which is confined to skin and subcutaneous tissues, and *systemic sclerosis* (systemic scleroderma), which affects both skin and internal organs (Box 140.1). In turn, systemic sclerosis (SSc) is divided into two major categories: limited cutaneous SSc, which is usually associated with mild to moderate, somewhat delayed organ fibrosis, and diffuse cutaneous SSc, which is characterized by correspondingly earlier and more severe organ damage.¹ This nomenclature has resulted in confusion among both physicians and patients, owing in no small part to the linguistic similarity between the words *localized* and *limited*. This chapter focuses mainly on systemic sclerosis, and the terms *scleroderma* and *systemic sclerosis* are used to refer to the systemic form of the disease unless otherwise specified.

CLASSIFICATION OF SCLERODERMA

The purpose of a disease classification schema is to facilitate accurate diagnosis, to provide reasonable homogeneity of subjects included in clinical research studies, and to predict prognosis reliably. Scleroderma offers a challenge in all these areas.

Box 140.1 provides an overview of the scleroderma classification. It should be emphasized that the 1980 preliminary classification for SSc developed by the American Rheumatism Association (ARA; now the American College of Rheumatology [ACR])² applies only to the systemic form of the disease.

Localized scleroderma

To the rheumatologist the term *scleroderma* refers to SSc, but to the dermatologist *scleroderma* refers to two separate conditions consisting of localized scleroderma and SSc. To further confound the situation, the term *localized*

scleroderma is remarkably similar to *limited scleroderma*, although these conditions are quite distinct. Because of this similarity in nomenclature, patients and physicians are frequently confused.

The use of the word *localized* in regard to scleroderma is meant to designate a fibrosing disease that affects the skin and underlying tissue (subcutaneous layer and occasionally underlying bone) but that does not affect internal organs (i.e., is not systemic).³ With the single exception of a very rare variant (pansclerotic morphea), localized scleroderma does not result in shortened survival.

As noted in Box 140.1, there are several subsets of localized scleroderma, and the schema outlined here is simplified. The most common form of localized scleroderma is plaque morphea and is characterized by patchy and well-circumscribed areas of thickened skin that can occur as a single lesion or as multiple lesions.³

Linear scleroderma (also known as *linear morphea*) refers to a distinct subset of localized disease that is characterized by a line of thickened skin usually involving an extremity. This is more common in children but can occur *de novo* in adults. If onset is in childhood, linear morphea can result in growth retardation of the affected limb and/or flexion contractures of underlying joints.

Scleroderma en coup de sabre (“cut of the saber”) refers not so much to a distinct form of localized disease but to the area of involvement—that is, the frontoparietal skin—and is characterized by a deep furrowing of the scalp and forehead, usually just to one side of midline. There appears to be an association with hemifacial atrophy (Parry-Romberg syndrome), although this may represent a separate entity.⁴

In addition to the features noted there are several other variants of morphea that are discussed in more detail in Chapter 147.

As noted earlier, for the most part, localized scleroderma is a skin and subcutaneous disease that does not affect internal organs and therefore does not shorten survival.³ However, linear disease in childhood can affect limb growth and can therefore have long-term functional sequelae. Scleroderma *en coup de sabre*, particularly when accompanied by hemifacial atrophy, can be a cosmetically devastating condition.

Finally, there is a rare variant of localized scleroderma called *pansclerotic morphea of childhood* (disabling pansclerotic morphea) that is characterized by rapidly progressive fibrosis of skin, subcutaneous tissue, muscles, and occasionally bone that can spread over the entire body, resulting in contractures, muscle atrophy, dermal ulcers, debility, and death.⁵ Although this has been considered a childhood disease, adult-onset cases have been reported.

Table 140.1 lists features that either distinguish localized from systemic disease or are common to both conditions. A positive antinuclear antibody test result and histologic findings of dermal fibrosis can exist in both conditions⁶ and therefore are not helpful in making a clear distinction. However, the presence or absence of Raynaud phenomenon and the pattern of skin involvement are the two most distinguishing characteristics. The presence of one of the three mutually exclusive systemic scleroderma autoantibodies (anticentromere, anti-topoisomerase I, and anti-RNA polymerase III) is very helpful in identifying systemic disease; however, only approximately 60% of patients with SSc have one of these autoantibodies, which makes these tests specific but not particularly sensitive.⁷

Classification schema for systemic sclerosis

The ARA established preliminary classification criteria for SSc in 1980 (Box 140.2).² These criteria were based on a multicenter prospective study of 264 patients with SSc and more than 400 comparison patients with other connective tissue diseases. The usefulness of the criteria is that they distinguish SSc from systemic lupus erythematosus and other autoimmune diseases. However, the criteria perform less well in capturing more mild forms of

BOX 140.1 CLASSIFICATION OF SCLERODERMA

- I. Localized scleroderma
 - A. Morphea
 - B. Linear scleroderma
 - C. Scleroderma en coup de sabre
- II. Systemic sclerosis
 - A. Limited cutaneous systemic sclerosis
 - B. Diffuse cutaneous systemic sclerosis

BOX 140.2 1980 PRELIMINARY CLASSIFICATION CRITERIA FOR SYSTEMIC SCLEROSIS

- A. Major criterion
 - Scleroderma (symmetric thickening) proximal to the metacarpophalangeal joints
- B. Minor criteria
 - 1. Sclerodactyly (symmetric skin thickening limited to the fingers)
 - 2. Digital pitting scars or loss of finger pad substance
 - 3. Bibasilar pulmonary fibrosis

Adapted from Appendix I: Criteria for the classification of systemic sclerosis (scleroderma). In: Klippel JH, Stane JH, Crofford LJ, White PH, editors. *Primer on the rheumatic diseases*. New York: Springer; 2008, p. 675.

TABLE 140.1 Comparison of localized scleroderma and systemic sclerosis

Feature	Localized scleroderma/morphea	Systemic sclerosis
Skin findings	Patches or linear distribution of thickened skin	Sclerodactyly ± proximal skin thickening
Raynaud phenomenon	Absent	Present
Digital ischemic changes	Absent	Usually present (digital pitting scars or ulcers, loss of finger pad substance)
Internal organ disease	Absent	Present
Antinuclear antibody	Present in ≥50% of cases	Present in ≥85% of cases
Scleroderma-specific autoantibodies*	Absent	Present in 60% of cases
Biopsy-histologic findings	Dermal fibrosis	Dermal fibrosis

*Scleroderma-specific antibodies include antibodies to centromere, topoisomerase I (Scl-70), and RNA polymerase III.

disease, particularly limited cutaneous SSc, and were established before the widespread availability of tests for the scleroderma-specific autoantibodies. In 1988 LeRoy and coworkers¹ suggested classifying SSc into limited cutaneous and diffuse cutaneous subsets. Limited cutaneous SSc was defined as skin thickening distal to the elbows and knees only, whereas diffuse cutaneous SSc involved thickening on the proximal extremities and/or the trunk in addition to distal thickening. Although distinguishing between limited and diffuse cutaneous SSc appears to be a simple and straightforward system, the situation is complicated by the fact that in some patients, over time, the skin can soften so that an individual who initially had a diffuse pattern early in the disease can have a limited distribution of skin involvement at a later time, typically several years after onset.

To better capture early disease, LeRoy and Medsger⁸ proposed a classification system incorporating nail-fold capillaroscopic changes and autoantibody results (Box 140.3). This system divides SSc into three subsets including limited SSc (without skin thickening), limited cutaneous SSc, and diffuse cutaneous SSc. However, this system has not been universally accepted. Thus there are various case definitions of SSc, which makes cross-study comparisons difficult to interpret.

BOX 140.3 2001 LeROY AND MEDSGER PROPOSED CLASSIFICATION OF EARLY SYSTEMIC SCLEROSIS (SSc)

Limited SSc: Objective documentation of Raynaud phenomenon plus either SSc-type nail-fold capillary pattern
or
SSc-selective autoantibodies (anticentromere, anti-topoisomerase I, antifibrillarin, anti-PM-Scl, antifibrillin, or anti-RNA polymerase I or III)
Alternative definition of limited SSc: Subjective reporting of Raynaud phenomenon plus both
SSc-type nail-fold capillary pattern
and
SSc-selective autoantibodies (as listed above)
Limited cutaneous SSc:
Criteria for limited SSc above plus cutaneous changes distal to the elbows, knees, and clavicles
Diffuse cutaneous SSc:
Criteria for limited SSc above plus cutaneous changes proximal to the elbows, knees, or clavicles.

TABLE 140.2 Clinical features and autoantibodies in systemic sclerosis

Feature	Anticentromere	Antitopoisomerase	Anti-RNA polymerase III
Limited cutaneous	Common	Less common	Less common
Diffuse cutaneous	Very rare	Common	More common
Interstitial lung disease (severe)	Rare	Common	Less common
Scleroderma renal crisis	Rare	Less common	More common
Pulmonary arterial hypertension	Common in long-standing disease	Unclear	Unclear

To date there has not been a simple, clinically feasible, and reliable classification system that can accurately subtype individuals to predict better or worse clinical outcomes. A combined effort of the ACR and European League Against Rheumatism (EULAR) currently is underway to update and integrate the different classification schemes to achieve a more uniform, accurate, and widely accepted case definition.

Classification based on autoantibody profile

Almost all SSc patients (85% to 90%) test positive for an antinuclear antibody on indirect immunofluorescence assay. In addition, most (60% to 70%) test positive for one of the three common scleroderma-specific and mutually exclusive autoantibodies for which tests are commercially available. These include anticentromere, anti-topoisomerase I (also known as Scl-70), and anti-RNA polymerase III antibodies. Antibodies to PM-Scl, fibrillarin, and fibrillin characterize a smaller proportion of SSc patients, and tests for these antibodies are not widely available.⁷ It should be noted that anti-RNA polymerase III is not the same as the anti-RNP antibody (anti-U1-RNP) that is associated with overlap syndromes, particularly mixed connective tissue disease.

In addition to being mutually exclusive, these autoantibodies tend to be present at the time of, or even before, symptom onset and rarely, if ever, switch during the course of disease.

Table 140.2 shows the major clinical associations with the three most common SSc-related autoantibodies. Anticentromere antibodies are the most reliable as indicators of limited cutaneous involvement, prolonged survival compared with diffuse cutaneous disease or subsets with other autoantibodies, and lower risk of significant pulmonary interstitial disease. However, these patients are at increased risk of developing pulmonary arterial hypertension as a later complication of SSc,⁹ so this should not be considered as a “benign” variant.

Autoantibodies to topoisomerase I (Scl-70) are more frequently seen in diffuse cutaneous disease but can be found in the limited subset as well and are relatively good predictors of severe interstitial lung disease.¹⁰

Antibodies to RNA polymerase III are associated more with diffuse rather than limited cutaneous disease and also confer a higher risk of renal crisis.⁷ However, renal crisis has been reported in patients with all antibody subgroups, even in those without antinuclear antibodies. It is prudent, therefore, to be vigilant in following scleroderma patients for this potentially life-threatening complication regardless of autoantibody status.

In summary, there is not yet a classification schema that will reliably predict the development and severity of internal organ disease at an early stage to permit more accurate prognosis, improve the design of clinical trials, allow more focused patient and family education, and dictate appropriate monitoring and treatment.

EPIDEMIOLOGY

Incidence and prevalence

The reported incidence and prevalence of SSc vary widely in studies conducted in different geographic areas and at various times. This variability may be due to differences in case definition and ascertainment methods but could also reflect true temporal and geographic differences. The reported prevalence of SSc in North America varies from 4 cases per million population for the period 1947 to 1952¹¹ to 443 cases per million in 2003.¹² Similarly, the annual incidence rates vary from 2.7 cases per million for the period 1947 to 1968¹¹ to 21 cases per million for the period 1989 to 1991.¹³ Table 140.3 summarizes the results of North American studies that reported incidence and prevalence of SSc over a 62-year period (1947 to 2009). Medsger and Masi¹¹ based their incidence rate calculation on 86 hospitalized patients from 1947 to 1968; the prevalence estimate was derived by multiplying the incidence rate by survival in years. Steen and coworkers¹⁴ determined incidence and prevalence based on 444 hospital-diagnosed cases in Allegheny County, Pennsylvania, over a 20-year period. Maricq and coworkers¹⁵ conducted a cross-sectional population survey in South Carolina, initially screening for the presence of Raynaud phenomenon and then performing a physical examination of responders who had that disorder. The prevalence was calculated based on only two cases that fulfilled the 1980 ARA SSc classification criteria.² Mayes and coworkers¹³ conducted a large-scale study in southeast Michigan from 1989 to 1991 using multiple sources of case ascertainment that included both inpatient and outpatient records and verification of diagnosis by chart review. Patients who fulfilled the 1980 ARA classification criteria² or had sclerodactyly plus two other features of CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) were included. A capture-recapture analysis was used to estimate the total SSc population. The resulting prevalence estimate was 276 cases per million adults (95% confidence interval [CI], 245 to 310). The same study reported an annual incidence rate of 21 new cases per million. Bernatsky and coworkers¹² estimated the prevalence of SSc in Quebec using physician billing and hospitalization databases. SSc cases were ascertained over a 10-year period, and the imperfect sensitivities of the ascertainment methods were accounted for by using a bayesian approach. The reported prevalence of SSc was 443 cases per million (95% CI, 411 to 476) in 2003. As shown in Table 140.3, there is a trend toward higher prevalence estimates in more recent studies, an observation that is related to multiple factors. The 1980 classification criteria

TABLE 140.3
Results of North American studies reporting prevalence and incidence of systemic sclerosis

Study	Period of observation	Prevalence (total cases per million)	Incidence (new cases per million per year)
Medsger and Masi (1971) ¹¹	1947-1952	4	0.6
	1953-1958	7	1.5
	1958-1962	21	4.1
	1963-1968	28	4.5
Steen et al (1997) ¹⁴	1963-1972	—	9.6
	1973-1982	—	18.7
Maricq et al (1989) ¹⁵	1985	286	—
Mayes et al (2003) ¹³	1989-1991	276	21
Bernatsky et al (2009) ¹²	1989-2003	443	—

enabled a uniform case definition across studies and the inclusion of milder cases that may have been missed in previous hospital-based studies. Additionally, the availability of computerized databases and increased awareness of SSc may have led to more complete case ascertainment in more recent reports. Furthermore, an improvement in survival of SSc patients as suggested by several studies^{13,16} would also lead to a higher prevalence as those surviving longer accumulate in the population. Nonetheless, the possibility remains that SSc may, in fact, be increasing in occurrence. However, both the Pennsylvania study¹⁴ and the Michigan study¹³ reported similar incidence rates for the periods 1973 to 1982 and 1989 to 1991 (19 and 21 per million, respectively).

Prevalence estimates and incidence rates vary greatly by geographic area. Table 140.4 summarizes several studies^{12,17-28} reporting the prevalence of SSc in North and South America, Asia, Europe, the United Kingdom, Scandinavia, and Australia. SSc prevalence varies from the highest estimate of 660 per million among the Choctaw Native Americans residing in Oklahoma to the lowest estimate of 38 per million in Japan. Direct comparisons of these figures is difficult due to the fact that some studies used the 1980 ARA classification criteria, others used the less restrictive LeRoy and Medsger criteria⁸ (see Box 140.3), and still others used the physician-reported diagnosis only. Therefore the wide variability of these prevalence estimates across the different geographic areas may reflect methodologic differences in case definition and ascertainment. However, it might also demonstrate true differences in prevalence of susceptibility genes or differential exposure to putative environmental triggers.

As indicated in Table 140.4, the highest prevalence was reported in a Choctaw Native American group in Oklahoma.¹⁷ In addition, the affected Choctaw cases showed a striking homogeneity in disease expression, with 92% of patients showing diffuse skin disease and 83% having antitopoisomerase antibodies. The strongest risk factor for SSc was a uniquely Native American HLA haplotype that was present in 100% of cases compared with only 54% of controls. A subsequent study showed that individuals with SSc were distantly related, which indicates that important susceptibility genes may have been inherited from common founders about 10 generations prior.²⁹

It is of interest that a study in Alberta, Canada, by Barnabe and coworkers¹⁹ also reported a higher prevalence of SSc among the First Nations group compared with the non-First Nations population in the same province, but this comparison did not reach statistical significance. It would be interesting to see if future studies of Native Americans also show an increased susceptibility.

Age at onset

The age at disease onset differs according to gender and ethnic background. The age at diagnosis is lower in female and in black patients.

TABLE 140.4
Results of selected international studies of systemic sclerosis in descending order of prevalence estimates

Study	Region or group	Prevalence (total cases per million)
Arnett et al (1996) ¹⁷	Choctaw Native American (Oklahoma, USA)	660
Kuo et al (2011) ¹⁸	Taiwan	563
Barnabe et al (2012) ¹⁹	First Nations people (Alberta, Canada)	470
